Dr. Charles E. Quimby said there was little to be said regarding an instrument which accomplished such specific results; he therefore did not believe that he had anything to say except to congratulate Dr. Lilienstein upon the work that he had done with this instrument. With reference to the electrocardiophone itself he had presented facts to the Section. Regarding phlebostasis, there were two points that he wished to impress upon all. First, one should forget the instrument; not to forget the instrument itself was, in his opinion, one of the great defects of the modern medical mind. He advised them to think more of what they were trying to accomplish and not so much of how they were trying to do it, that was, how to retain a certain amount of blood in the peripheral circulation. Secondly, he said he had had a desultory experience covering twenty-five or twenty-eight years in controlling the circulation and he had sometimes suggested this point, that the holding of blood in the two arms did affect the heart, and when the blood was let out there was a sudden flow of blood to the lungs. The apparatus in certain cases

raised the blood pressure, but it also lowered the blood pressure when it was already high, and for this reason; If the heart got just a little chance to rest it had a chance to pull itself together and could do so wonderfully; the heart seemed to be eternally grateful for this chance for rest and picked up marvelously, even if the amount of rest was little.

Dr. George Mannheimer said there seemed to be a great divergence of opinion with regard to the kind of cases in which this instrument should be used. They had an instrument of this kind by which one could exactly determine the venous pressure in every case. In cases where one could extract large quantities of blood, the limbs might be tied, a custom which had been used for years in pulmonary hemorrhage. Other instruments were used because they did not interfere with the ordinary circulation as much as did the one just presented with the cuffs.

Dr. Alfred E. Cohn said that at the Rockefeller Institute they registered the heart sounds by means of the microphone and with it they had more success than with the instrument shown by Dr. Lilienstein. It could be used for purposes of clinical investigation. A number of years ago he was struck by the fact that digitalis caused a heart block and when given in mitral stenosis there was shown a presystolic murmur which was made by the contraction of the auricle. A discussion of long standing ensued as to whether this was presystolic and made by the contraction of the auricle, and whether it occurred at the first portion of ventricular systole. The use of the microphone could, in his opinion, be extended and aid them in clearing up many obscure cases.

**Exhibition of a Patient Showing an Unusual Sign.**—Dr. Rolfe Floyd presented a patient who had an unusual sign over the junction of the first rib and column of the right side. There was a peculiar whistle at that point. The patient entered Bellevue Hospital two months ago complaining that for one year he had had a cough with white and yellow sputum which not infrequently was streaked with blood. The cough was intermittent. In addition he complained of intense pains in the chest which were not sharply localized. He stated that he was in ill health and unable or unfit to work. He did not lose weight. There were no tubercle bacilli in the sputum, he had no temperature and had nothing beyond what he stated on admission. On physical examination there was found nothing beyond this whistling sound which occurred at the junction of the first rib with the column on the right side; the sound was continuous, and more intense with systole and less so in diastole. It did not change in ordinary respiration. Sometimes in exercising with the arms it would disappear temporarily. The quality of the sound was high pitched and sibilant, frequently musical. One gentleman thought there was a tuberculous infiltration of the right upper lobe; personally Dr. Floyd was skeptical regarding this. Plates were shown which gave no explanation of the sound. He was at a loss how to interpret the sound. By some it was thought that it might be made in the blood vessels, but this was thrown out. Others thought it might have been made in the smaller bronchi in the upper part of the right lung secondarily dependent upon pulsation occurring in some disease or in normal vessels which lay against the apex. Dr. Floyd asked for some suggestions regarding the interpretation of this peculiar sound.

The following were contributions from the medical wards of the New York City Hospital:

**Exhibition of a Patient with Hypopituitarism.**—Dr. R. A. Cook presented a woman, forty-five years of age, who was admitted to the hospital April 4, 1912. It was impossible to get an accurate history because she was not visited by friends and her mental condition was quite below par, thus making a good history unavailable. She stated that she had been married but had had no children. Her family history was negative. Her habits were good. She denied ever having had in the past any illness of any kind. There was no alcoholic nor venereal history. Her menses ceased when she was thirty-eight years old. Three months before her admission to the hospital she complained of intense headaches and at the same time pains in the feet, legs and shoulders. When seen in August last she appeared just as she now appeared before the Section except that her mental condition was worse. She was an irritable but somnolent woman, lying in bed groaning with pain referred to her head, with expression dull, mentally much below par, weight 145 pounds and height 4 feet 7 inches. It was impossible to get her to speak at all rationally. In many ways this was a very interesting case. She was over-nourished. She had an extremely large head and a peculiar condition of the lower jaw; there were spaces between the teeth of both the upper and lower jaws. There was a moderate amount of exophthalmos. There were no motor manifestations. It was impossible to examine her eye grounds. There was no nystagmus, nor oculomotor palsy. Vision showed right 5/20 and left 5/30. Perimetric deviations were not made. The heart was normal. There was a blood pressure of from 160 to 170. She passed from 30 to 40 ounces of urine daily in which there was some albumin and a few hyaline casts. The condition of the blood was somewhat peculiar, in which there was from 8 to 19 per cent. eosinophiles. There was no increase in the leucocyte count. A test was made of her carbohydrate tolerance, 350 grams of levulose being given; this was not followed by any appearance of sugar in the urine at all. She had no subnormal temperature, as many of these cases had. She had a very marked adiposity but there was no increase in the size of the hands or feet. The *x*-ray pictures of head and teeth were shown. Also pictures of the sella turcica, first of the normal and then of what the patient presented, in order that a contrast might be demonstrated between the normal and the abnormal. In the treatment of this patient pituitrin had been used, but with no improvement. The question of operation was a difficult one to answer. Dr. Cooke thought that the use of the posterior lobe extract of the pituitary gland was possibly the best treatment. At present the patient appeared to be much better, having no headaches and with a normal vision.

**An Unusual Case of Syphilitic Nephritis, Hepatitis, and Myocarditis.**—Dr. Harlow Brooks reported this case. The patient was a man, 63 years of age, who entered the hospital in February, 1911. His family history was unimportant. He had had rheumatism ten years previous and typhoid fever seven years ago. He was a moderate user of alcohol and tobacco. He denied absolutely any history of venereal infection or any skin or mucous membrane symptoms which might be construed as of syphilitic origin. His chief complaint was shortness of breath, especially on exertion, which was associated with pain in the pericardium, headache, swelling, and cyanosis of the hands and feet. The right pulse was very small and indistinct and was absent for most of the time. The left pulse was regular, the artery being plainly palpable and thickened. The respiratory movements were shallow, rapid, and accompanied by sibilant râles, apparently without auscultation. The apex beat was visible and palpable in the fifth interspace and four inches to the left of the midsternal line. The right cardiac border lay one and one-half inches to the right of the midsternal line. The heart sounds varied greatly in rhythm, and in the occurrence, disappearance, and location of murmurs. The thorax presented considerable bulging and enlargement of the left side. There was a broad area of dullness beneath the manubrium sterni but no tracheal tug or abnormal suprasternal pulsations. There was enormous distention of the superficial thoracic veins, and of those which communicated with the radicles of the superficial epigastrics. Liver dullness extended about one hand's breadth below the costal margin. The liver was very firm and somewhat tender. The abdomen contained considerable fluid. Examination of the blood showed a constant polycythemia. The urine showed the continuous presence of albumin, epithelial, and occasionally blood cells. A diagnosis was made of aneurysm of the transverse arch, myocarditis, cirrhotic liver and spleen, with secondary nephritis and polycythemia. Radiographs verified the diagnosis of aneurysm of the transverse arch. Syphilis was assumed to be present, but the Wassermann reaction was at first reported negative, but after treatment had been instituted was found to be strongly positive. The patient had a strong intolerance for the iodides, so salvarsan was used; his condition improved markedly under this treatment together with heart stimulants. In November he developed a gangrene of the right foot and a diagnosis of embolism from a detached cardiac or aneurysm clot was ventured. Death soon followed. At autopsy the retrosternal mass was found to be a widely dilated but not sacculated arch, which together with the entire artery was very extensively diseased and ulcerated; the ulcerations were in a healing and not a progressive state. The heart was greatly enlarged and showed a diffuse interstitial myocarditis with occasional small gummatous scars undergoing rapid fibrosis. The small pulse on the right was explained by a very old thrombosis with a subsequent canalization of the right brachial artery. The liver was greatly enlarged and showed the results of chronic congestion; there were frequent healed gummatous scars. The spleen was indurated and enlarged, and the kidneys showed a diffuse fibrosis with nodules of compensatory parenchymatous hyperplasia. Realizing that microscopic study of this process might give a clew as to the manner in which healing might occur in the heart

muscle in syphilitic myocarditis under the effects of salvarsan, such a study was made. Microscopical examination of the heart showed in the main considerable atrophy, which with certain exceptions seemed to have been of pressure origin and not due to inherent disease of the muscle cells. For the greater part striation was well preserved; there were a good many enlarged and karyokinetic nuclei, but cytoplasmic alterations were mostly wanting excepting in the cells of the papillary muscles where brown atrophy was quite general. The connective tissue interstitium was universally increased. This applied not only to the endomysium, but also to the connective tissue of the endocardium and epicardium. It was notably evident that hyperplastic connective tissue was most abundant and the evidences of recent growth were most manifold about the arterioles of the coronary trunks. A further peculiarity of this interstitial overgrowth was its highly cellular character, as though of rapid and recent formation or true scar formation; it was not present execept in the papillary muscles and in the foci of old gummatous inflammations. Very few infiltrating leucocytes or wandering connective tissue cells were present and even about the blood channels very few indications of inflammation were to be made out. Lymphocytes were exceedingly few in number in both the connective tissue and the walls of the vessels except in the papillary muscles where foci of infiltration and actively hyperplastic cells were present. Connective tissue necrosis was also infrequent. Notwithstanding the fact that gross examination indicated that the coronary vessels were not markedly involved, the microscopic sections showed that the walls were very much diseased. The scars found at various points in the heart wall and apparently representing the sites of old gummata showed under the microscope a replacement process of the muscle by a growth of young areolar tissue like that found elsewhere in the specimens. There was nothing anywhere evident indicating activity of the process and nothing to signify that it was a syphilitic process. Spirochetes could not be demonstrated in any of the sections. Sections of other viscera showed almost universally similar changes. The picture of the entire process was one of definite and rapid healing and one which was apparently taking place with the minimum injury to the surrounding parenchymatous tissues.

**Report of Two Cases of Hodgkin's Disease, One with Specimens.**—Dr. EDMUND P. SHELBY reported these cases. Among the noteworthy points were the following: (1) The duration of the disease, ten and one-half months. (2) The febrile onset. (3) The slight changes in the superficial lymph nodes no one of which was as large as a bean. (4) The marked efforts at repair as shown by the healing of the wound and diminution of the abdominal mass, gain in weight, and an unusual amount of hyaline fibrous tissue in the lymph nodes and viscera. (5) The continuous fever which did not reach normal until a few days before death. (6) The absence of gastrointestinal symptoms in spite of the high temperature and marked involvement of the abdominal nodes. (7) The limitation of the process to the abdominal lymph nodes and the viscera. (8) The occurrence of herpes zoster with hemorrhages into the spinal canal and degeneration of certain areas in the posterior nerve roots. (9) The convulsions and other evidences of marked toxemia toward the end. (10) The peculiar gelatinous tissue surrounding the membranes of the cord and the abdominal chain of lymph nodes. (11) The extreme difficulty of diagnosis even after a lymph node had been removed. (12) The absence of any positive evidence of tuberculosis. (13) The negative result of the Wassermann and von Pirquet reactions.

**Report of a Case of Mediastinal Tumor, with Specimen.**—Dr. R. GARFIELD SNYDER reported this case because of the difficulty in making a diagnosis. The chief complaint of the patient was his inability to work because of cardiac weakness which had existed during the past six months and which appeared to be progressive. The apex beat was on the opposite side of the chest and it was at first thought to be caused by a congenital displacement of the heart, a retracted right lung, an empyema of the left side, or perhaps an aneurysm, or a distended aorta. Dr. Cooke thought the condition might possibly be a diaphragmatic hernia because there was some tympany high up in the axilla. The condition was also thought to be due to some tumor, as a cyst. Dr. Le Wald made some *x*-ray pictures which were shown. A needle was thrust into the mass and a peculiar fluid was withdrawn; none of those present had seen a similar fluid. It was very thick, very gelatinous, and almost resinous in appearance. It reminded one of a thick syrup and was so thick that very little could be obtained. This patient was under observation for about three months and the *x*-ray pictures showed that the tumor was gradually increasing in size. The patient not only asked for operation but demanded it. The tumor was a fibromyxoma independent of diaphragm, thyroid, or thymus.

**Experience with the Use of Phenolsulphonephthalein in Clinical Medicine.**—Dr. ORRIN SAGE WIGHTMAN gave a brief description of the technique. One c.c. of the intensely red coloring matter of phenolsulphonephthalien was injected in fluid form into the deep muscles of the back, preferably the quadratus lumborum. Twenty minutes before the injection the patient drank a glass of water to promote free diuresis. The patient had already emptied the bladder or had been catheterized. If the catheter had been used it was left in place and a pan placed where the first urine secreted might be caught. In the pan were a few drops of caustic soda which promptly discovered the presence of color when passed from the bladder. This told the speed of the elimination after the muscular injection. If the ureters were catheterized instead of the bladder, the same method obtained. At the end of the first hour all available urine was collected in one bottle and represented bottle No. 1; at the end of the second hour they obtained specimen No. 2, and at the end of the third hour specimen No. 3. Roundtree and Geraty stated that the secretion was complete in two hours, but in their experience they had recovered color even after twenty-four hours. The object of the test was to recover as much of the color as possible, as 100 per cent. represented a perfectly normal kidney function. The colored or partly colored urine obtained was rendered alkaline with caustic soda to bring out all possible color and by proper dilution was compared in a special instrument with a standard solution of phenolsulphonephthalein. The apparatus for this comparison worked on the same principle as the Fleishl blood scale, viz., a comparison of color with a standard. When the percentage of color in the urine matched the standard solution it was read off on a scale on the side of the instrument. Naturally there arose a question of exact reading, but if the same man made a series of constant observations with the same technique there was usually not more than 5 per cent. variation which was near enough to be useful. The cases that had claimed their attention in these tests had all been cardiorenal, with the exception of those taken as a control to see how far the color might be eliminated from an apparently normal kidney. In the series observed they had carefully considered the age, sex, diseases of childhood which might have previously rendered a kidney or heart vulnerable, the family history, and the careful history of the patient's symptoms since coming for treatment. Where it had been possible a Wassermann test had been taken, the blood pressure followed, and an examination of the urine made with special regard to albumin, urea, indican and the microscopical findings. By following the above method a comparison of the results became more valuable, as shown by charts. From a clinical standpoint one was anxious to know how much of the kidneys were entirely active rather than to make the closer differentiation of the variety of nephritis. While the small number of cases were entirely insufficient for any conclusions, they were suggestive of the following: The amount of color voided told what the kidney was secreting at the time of the test. The picture of nephritis was an individual one and rarely of any strict class or subdivision. The elements entering into it gave merely class distinction by emphasizing either parenchymatous or interstitial elements. An apparently normal kidney secreted a high percentage of the coloring matter, while a diseased one did not.

Dr. CHARLES GOODMAN said that in 1910 he obtained phenolsulphonephthalein and in the fall of the same year he presented before the Section on Genito-Urinary Surgery his results in the use of this test. In certain cases such as double renal calculi, where the question arose as to which side should be operated upon, the results obtained from this test increased one's confidence in its efficacy.

**Pancreatic Lesions in Diabetes.**—Dr. JOHN H. LARKIN gave a demonstration of gross specimens from the Strecker Memorial Laboratory, among which were the following: Syphilitic pancreatitis in which the lesions were very marked. There occurred many cases of pancreatic apoplexy in cases of this nature. There was another type in which the sclerosis was well marked, with an almost entire displacement of the pancreatic tissue by the fibrous tissue; in many of these cases small cysts formed along the ducts. Another pancreas he showed was one in which the pancreatic tissue was naturally preserved, but showed in certain places an interlobular fat infiltration. Still another pancreas was one in which the insular sclerosis was but partial and caused functional disturbances and nerve irritation.

### ON THE OCCURRENCE OF DEXTROROTATORY ALBUMINS IN ORGANIC NATURE.

By JOHN BEARD, D.Sc.,

EDINBURGH, SCOTLAND.

TWENTY-FOUR years ago the discovery of a transient nervous apparatus in the developmental histories of certain fishes directed my attention to the problems of alternation of generations in general, and of antithetic alternation in particular. Research in the intervening years was devoted mainly to the unraveling of the thread of animal development regarded as based in such an antithetic alternation of asexual and sexual generations. A review of the problems, which occupied the investigator during these years, and of their solutions, cannot be given here: the finds are recorded in the literature of science and most of the salient points may be found in detailed form in the memoirs, cited below.[1] These commence with "The History of a Transient Nervous Apparatus" and end in "The Enzyme Treatment of Cancer."

To the investigator, groping slowly along an untrodden path, it was of very great value, when, in 1907, it was recognized that the antithetic alternation of generations, which by observation had been found to underlie the cycle of animal development, was in reality based in the same antithesis of isomeric compounds of carbon as that laid bare by the epoch-making researches of Pasteur. These, as is well known, culminated in the foundation of a science of stereochemistry. Since 1860 stereochemistry has been advanced by the researches of many chemists, and here of these the names of LeBel, van't Hoff, Wislicenus, and Emil Fischer need alone be mentioned.

Modern embryology, like modern zoology in general, has concerned itself little with chemistry. As can be perceived now, many questions, which have troubled embryologists and zoologists, might have been settled easily once and for all and long ago had the contending investigators occupied themselves with the problem of the true chemical nature of the animal under discussion instead of assuming that of necessity all animals were alike in chemical nature and composition. The embryology of Carl Ernst von Baer and of his successors until recent times was exclusively a descriptive science based in observation. There was, indeed, but a single criterion by which anything embryological could be determined, and that was the fate of the cells concerned. But since in any developing "germ" the cells composing it are living, all questions concerning their fate during development are bound up with chemical, and indeed stereochemical, problems which demand answers.

In 1906 it first dawned upon me that in organic nature there must exist *at least* two sorts of living albumins, lavo- and dextrorotatary respectively, and in 1907 the conclusion was published, that the albumins of cancer and of malignant tumors in general must be dextro bodies, because of the destructive action, ending in liquefaction, of active pancreatic ferments, especially trypsin, upon them. Because of all this it became desirable to demonstrate, and by some method above reproach, that dextrorotatory albumins, similar to those of cancer, did exist, and, indeed, were widely present in other portions of organic nature. With this end in view in the summer of 1912 I began a series of experiments and now record some of the results. The vastness of the fields of animal development and of the unicellular animals or protozoa would, no doubt, permit of a wide series of experiments, but to carry out very full series would require much time, material, and financial means not at my disposal.

There are several ways known by which stereochemical questions can be solved. Of these two only need be referred to as connected with the present inquiry. These are (1) examination of the optical rotations of isolated (dead) liquid albumins in the polarimeter, and (2) the "lock and key" method, that is, the positive or negative action of certain ferments, as employed by Emil Fischer. Regarding the first, the isolation of the albumins in a state suitable for the study of optical rotation is beset with great intrinsic difficulties, more especially in dealing with minute microorganisms. Since all living matter is bound up with, and depends upon, the action of ferments, it is anything but easy so to isolate the albumins that they do not undergo autolysis or self-digestion quickly. The second method, that of the action of ferments, is much simpler in practice, and there only remains for brief discussion the reliability of this method of investigation, the question of how far it is to be considered as being a severely scientific criterion.

Probably today a stereochemist would not admit that these matters were open to doubt or discussion, but mindful of the circumstance that these lines are written for readers of whom many are not conversant with the facts of stereochemistry, it may not be superfluous to adduce reasons. One may read—I have myself written it—that "a ferment fits the substance upon which it acts 'as a key fits a lock.'" This simile, and the foregoing thesis, we owe to the genius of Emil Fischer. The dictum is quoted not infrequently, but, as happens with other classic scientific quotations, at times one may doubt whether the citation was made after a study of the original memoirs. It is an excellent rule to verify one's citations and that I propose to do in this instance.

Since it is my contention that the original words and proofs adduced by Professor Emil Fischer suf-

fice amply to establish the legitimacy of this scientific test by means of ferments, and to make it at least equal in value to the test of the optical rotation in the polarimeter, it may be well worth while to give some account of Fischer's fundamental researches upon the question, and in his own words. This is all the more desirable in that, to my knowledge, there is at present in the English language no concise account of how Fischer arrived at the simile of "lock and key," on what cogent evidences its truth was based. A search of the chemical literature of the matter under discussion will show that the main facts and conclusions are contained in three memoirs. Of these two will be found in one immense volume (Vol. 27) of the Reports of the German Chemical Society, and the third in the twenty-sixth volume of the *German Journal of Physiological Chemistry*. The first paper bears the date 1894 and treats of the behavior of different sugars toward pure yeasts. From p. 2036 the following citation is taken: "That microorganisms generally of two optically isomeric compounds prefer the one has long been known from the investigations of Pasteur and others; but with the yeasts and the sorts of sugars the matter lies somewhat differently, since here it is not alone a question of the antithesis of two optical antipodes, but out of a great number of geometrical forms some only satisfy the needs of the cell. It may be anticipated that the same observation will be found in other microorganisms, and, moreover, in other groups of organic substance, as perhaps very many chemical processes, which happen in the organism, are influenced by the geometry of the molecule. Under these circumstances it is worth while to seek after the reason of the phenomenon, and it lies on the surface that the explanation is first of all to be sought in the region of stereochemistry.

Among the agents which the living cell makes use of the different albuminous substances play the chief rôle. They are also optically active, and since they arise synthetically from the carbohydrates of plants, one may, indeed, conclude that the geometrical build of their molecule, in respect of asymmetry, is in essentials similar to that of the natural hexoses. Under this conclusion it is not difficult to understand that "*the yeast-cell with its asymmetrically formed agent can only attack, and force into fermentation, the sorts of sugars the geometry of which departs not too far from that of grape-sugar.*"[2]

The second memoir bears the date Oct. 29, 1894, and in it, under the title "The Influence of the Configuration upon the action of the Enzymes," the author, Prof. Emil Fischer, set up the simile of "lock and key" in the course of the following discussion (on pp. 2992-2993: "But the observations suffice already to approve (the principle) that with respect to the configuration of their objects of attack the enzymes are just as elective as the yeasts and other microorganisms. In this respect the analogy of both phenomena appears so complete that one may adopt the same reason for it, and with this I return to the hypothesis of Thierfelder and myself, already referred to. As is well known, *invertin* and *emulsin* have many resemblances to the proteid stuffs, and like these they possess an asymmetrically built-up molecule. Their restricted action upon the glucosides would permit of explanation by the supposition that only with similar geometrical build can that approach of the molecule take place which is requisite for the resolution of the chemical process. To use a simile, I should like to say that enzyme and glucoside must fit each other like lock and key in order to be able to exert a chemical action upon each other. This conception has certainly gained in probability and in value for stereochemical investigation since the phenomenon itself has been transferred from the biological to the purely chemical region. It forms an extension of the theory of asymmetry, but without being a direct consequence of it, for the conviction that the geometrical build of the molecule even in looking-glass image forms should exercise so great an influence upon the play of the chemical affinities could, in my opinion, be gained only by new observations founded on fact. The experience hitherto, that the salts composed of two asymmetrical compounds may differ in solubility and melting point, would certainly not suffice for it. That the fact established now for the complicated enzymes will also soon be found for the more simple asymmetrical agents I doubt as little, as the usefulness of enzymes for the ascertaining of the configuration of asymmetrical substances.

"The experience that the efficacy of the enzymes is restricted in so high a degree by the molecular geometry ought also to be of some use for physiological investigation. But still more important for this appears to me the proof that the difference previously accepted between the chemical agents in respect of molecular asymmetry does not exist. Thereby the analogy emphasized especially by Berzelius, Liebig, and others of 'living and lifeless ferments' is again set up in a not unessential point."[3]

The third memoir, by Prof. Emil Fischer, is a summary of the chief points of the two earlier ones, and in it (p. 81), under the heading "Theoretical Considerations," the author writes: "But the enzymes are quite especially valuable, as I first emphasized, as means of recognition of stereochemical differences, and with this I come back to the object, which I consider to be the most important result founded upon fact of my experiments. These furnish the unchallengeable proof that of two molecular looking-glass image forms the one is broken up by enzymes under the same conditions under which the other remains intact. For this there are two examples, the behavior of β—methyl—d—glucoside (*minus*) and of β—methyl—l—glucoside (*plus*) towards *emulsin*, and the behavior of α—methyl—d—glucoside (*plus*) and of α—methyl—l—glucoside (*minus*) towards the enzyme of yeast." On p. 82 "The ground of these phenomena lies in all probability in the asymmetrical build of the enzyme-molecule. For although these substances are not yet known in pure form, their similarity to the proteid stuffs is so great and their origin from these latter so probable, that undoubtedly they are themselves to be regarded as optically active and thus asymmetrical molecular structures. That has led to the hypothesis that between enzyme and its object of attack a similarity of molecular configuration must exist, if a reaction shall ensue. In order to make this thought intuitive, I have used the simile of lock and key."

Further, on p. 84, we read: "If one carry this over to the chemical processes of the higher developed organism, one arrives at the conception, that generally in the transformations, by which the proteid stuffs function in active masses, as undoubtedly that is the case in protoplasm, the configuration of the molecule frequently plays just as great a rôle as its structure. For this reason it is no longer astonishing that of two stereoisomeric substances the one reacts strongly upon our sense organs, such as taste and smell, while the other is quite indifferent, or produces a very much weakened reaction."[4]

In the foregoing citations there are two things to which I would direct special attention. The first is the repeated emphasis which the author lays upon the use and value of ferments as reagents for the determination of stereochemical differences, and the other the number of experiments, to wit, two, from the positive results of which the investigator maintained the establishment of his thesis, that "of two molecular looking-glass image forms the one is broken up by enzymes under the same conditions under which the other remains intact." It may suffice for an embryologist, who is not a stereochemist, to refer to the works and researches of this distinguished chemist, Emil Fischer, for the scientific reasons for the employment of enzymes or ferments as testing agents. As to the second point to be noted, Fischer's two experiments in proof of his thesis remind one of Pasteur's words, "If a doctrine be challenged, it happens seldom that its truth or falsehood cannot be established by some crucial test. Even a single experiment will often suffice either to refute or to consolidate the doctrine." In the following, as proving to the hilt the truth of my thesis, that dextrorotatory albumins occur, and, indeed, are widely represented in organic nature, several experiments and their positive results will be adduced. Here it may be added, that the cases described under the experiments are only a few, taken at random, merely because the organisms dealt with happened to be accessible readily, and that the number can be increased to any extent desired, on due cause being shown. He who may feel inclined to contradict the thesis, can by taking the trouble to repeat and extend my experiments, using the same Fairchild preparations, and as I have employed them, convince himself that his contemplated contradiction and refutation are futile.

A condition of all the experiments is that the microorganisms used should be in an active healthy state. It would, of course, be feasible to carry out the experiments to a successful issue with much smaller quantities of ferments, provided the experiments were made at a higher temperature, for instance, at blood-heat or between 38° and 40° Centigrade. It was, however, more convenient to make the experiments at the ordinary temperature of a room, and with such dilutions of the combined ferments, trypsin and amylopsin, as would enable their deadly disintegrating effects upon healthy living asexual microorganisms to be observed, as a rule, within the space of an hour or less. It is, be it remarked, quite unnecessary for any critic to point out that the finds recorded here could have been obtained by the use of trypsin alone without the aid of amylopsin. Of that fact I am aware. But the reason why amylopsin was also invoked in the experiments was because I thought, and shall always think, that the use of trypsin alone in the treatment of cancer, various tropical diseases, tuberculosis, etc., is a very dangerous proceeding, even in many cases a deadly one. I wished, therefore, to avoid doing anything to encourage a belief that in the practice of medicine trypsin without the aid of its complement, amylopsin, could be regarded as a safe and efficacious remedy.

The reagents and the conditions under which they were used were as follows: Since there are on the market preparations, even injections for use in medicine, of pancreatic ferments, trypsin and amylopsin, which are either excessively weak, or unreliable, or even quite inert, it was necessary to take for the experiments such injections of trypsin and amylopsin in combination as were strong, of known strength, standardized, and of a stable character. As W. Bätzner[5] has shown, the most powerful, reliable, and stable pancreatic injections are the ones manufactured by Messrs. Fairchild Bros. & Foster. To distinguish them from earlier and weaker injections made by the same firm, they will be referred to here as the Fairchild "1912" injections of trypsin and amylopsin. These injections are standardized in various ways, not in a single one, and thus it is possible to refer to the trypsin-injection, for example, as Bätzner does, as possessing a potency in dilution of 1 : 4000, tested by the Jochmann method, or by the Roberts methods as containing per cubic centimeter 1250 tryptic units, while the amlopsin-injection, which like the trypsin-injection is of maximum potency, possesses per cubic centimeter 500 units of amylolytic activity. The procedure was to mix the contents of an ampoule of each of the ferments, trypsin and amylopsin, and then to dilute the fluid with clean fresh rain-water, until the bulk of liquid equaled ten cubic centimeters. This stock-fluid, freshly prepared for each occasion, was further diluted as described under the account of the experiments. These latter were made in watch-glasses, containing the organisms and a given number of drops of clean fresh rain-water, to which at a given time a certain amount of the diluted ferments was added. On all occasions the temperature of the room was noted. The changes are quite easily observed under the microscope, and except with such forms as *Amœba* no higher power than a Zeiss AA is needed. In instances like *Amœba* it is more convenient to use a slide with a deep cell in it and to cover the preparation. Here also higher powers of the microscope are called for. The ampoules used contain somewhat more than one cubic centimeter, and in instances measured accurately the contents of the two ampoules before dilution totaled 2½ cubic centimeters. It should be added that these preparations are stated to be put up in a menstruum of 60 per cent. glycerin, and that they contain no antiseptic. No statement is made in the present writing that any other pancreatic preparations upon the market used in the like dilutions will give the same results. The finds are recorded for certain specified pancreatic preparations, and for these only, and used as described here. The necessity of this warning may be judged from the fact that even in the present year 1912 ampoules of injection, labeled "trypsin," have been offered for sale in Great Britain, and on assay it was found that all the "trypsin" connected with them in any way was contained in the label.

I. *Hydra fusca.* Temperature of room 19° C. Two individuals of the common fresh water "polype," *Hydra fusca*, in nine drops of clean fresh rain-water. 11.8 A.M. Added one drop of the 10 c.c. dilution of T. & A., and allowed this to diffuse through the water. Contraction of the animals in one minute or less. 11.14. Slight expansion, then contraction, tentacles knobbed. 11.15. One animal contracted, the other somewhat expanded, but anterior part of body strongly contracted. 11.18. Both much contracted. 11.19. In one a tentacle in disintegration. 11.20. Bodies pilose, as though stinging-cells had shot out. 11.31. Both much digested and tentacles becoming indistinguishable. 11.45. Greatly disintegrated, and cell-remains breaking away. 12.12. Shockingly disintegrated. Experiment ended.

II. *Hydra fusca*, and its unicellular parasite,

*Trichodina pediculus*. Same day and like solution. Three specimens of the common hydra, *Hydra fusca*, infested with parasitic *Trichodina*, in ten drops of clean fresh rain-water. 11.36. Added five drops of the 10 c.c. solution of T. & A. 11.38. Polypes contracted strongly. Two parasites moving on one. 11.39. Tentacles of polypes twisted at ends. 11.40. Parasites gyrating slowly on one polype. 11.41. Parasites dead and fallen off. 11.42. Parasites dissolving and their nature no longer recognizable. 11.50. Tentacles of polypes breaking up. Experiment ended.

III. *Vorticella*. In ten drops of clean fresh rain-water. 11.52. Added one drop of the 10 c.c. solution of T. & A. 11.54½. Vorticellids still moving. 11.55. Movements slight, more gyrations. 11.57. More vigorous short, not elongating, gyrations. 12 noon. Individuals fully extended. 12.2. Slow contractions, not complete, remaining half-way. 12.4. Individuals all dead, that is, in ten minutes. 12.10. No movements, clarifying and in disintegration. Experiment ended.

IV. Various flagellate "monads." Same day. Ten drops of water, containing many flagellate "monads." 12.40. Added one drop of the 10 c.c. dilution of T. & A. All movements cease at once. Experiment ended.

V. *Amœba* and Crustacean "*nauplii*." Same day. *Amœba* in a cell with five drops of water. 12.48. Added one drop of the 10 c.c. solution of T. & A. There were many *Amœbæ* in this fluid. 1.2. *Amœba* contracting. 1.6. Another *Amœba* apparently in disintegration, no movements. 1.12. No *Amœbæ* moving, where seen always contracted. At 9 P. M. on the same day, that is, eight hours later, two Crustacean "*nauplii*" were still swimming about in this mixture of water and ferments, and there were no traces of *Amœbæ*. A Desmid appeared to be unaltered.

VI. *Hydra fusca* and *Trichodina*. Room temperature 18° C. A stock-solution of 10 c.c. of T. & A. was made up (A solution). Of this 2 c.c. were nearly boiled to destroy the ferments, and as the result a turbid mixture and flocculent precipitate were obtained. This was filtered to obtain the menstruum of the ferment-solution (B solution). 10.13. Two watch-glasses, each containing two *Hydra fusca* in ten drops of clean fresh rain-water. 10.15. Added to watch-glass No. 1 one drop of the A solution, to No. 2 one drop of the B solution. Phenomena observed in No. 1. 10.17. The parasitic *Trichodinæ* have dropped off the *Hydra*. 10.20. One *Hydra* much contracted. 10.23. Both *Hydræ* much contracted and one pilose. 10.45. Both *Hydræ* much macerated. This portion of experiment ended. Phenomena observed in No. 2. 10.22 A. M. *Trichodina* still alive and moving on hosts. 10.45. *Hydra* still alive. 11.15. *Hydra* still alive, fluid removed, and fresh rain-water given. This portion of experiment ended. Comparison of the two portions shows clearly that the menstruum (glycerin) was not answerable for the deadly disintegrating effects observed.

VII. Various undetermined flagellate microorganisms. Same day. One drop of the stock-solution of T. & A. added to twenty drops of water. 11 A. M. Of this mixture one drop added to various flagellate microorganisms in a cell. 3.30 P. M. All the flagellate organisms dead, but various "swarm spores," which are vegetable, not animal, were still alive and active.

VIII. *Amœba*. *Amœba* in a cell with three drops of water. 12.2 P. M. One drop of the 10 c.c. solution of T. & A. added. 12.8. *Amœba* found under the microscope, and in movement 12.15. Appears to be contracted and not moving. 12.22. Slight movements. 12.27. Globular, no pseudopodia, gyrating slowly. 12.31. Still globular. 12.33. Slight alterations in shape, but no pseudopodia. 12.37. Floating freely in the water, and apparently dead. 12.38. Nucleus escapes. *Amœba* seems to be breaking to pieces. 3.15 P. M. Still much the same, but obviously the cytoplasm has all gone, and what is left is mainly made up of products of excretion, vacuoles, diatoms, etc.

IX. *Hydra fusca* and *Trichodina*. One *Hydra* in a cell with many parasitic *Trichodinæ*. 2.48. Added one drop of the 10 c.c. dilution of T. & A. to three drops of clean fresh rain-water. *Hydra* contracts at once, and to all appearance is killed instantaneously. The parasites also seem to be killed at once, and they begin quickly to disintegrate. 2.52. Tentacles of *Hydra* in disintegration. 3.16. *Hydra* is a shapeless mass, and the ectoderm is nearly all dissolved off. Experiment ended.

X. *Hydra fusca* and *Daphnia pulex*. Temperature 17° C. Two watch-glasses, the one containing two *Hydra* and a few *Daphnia*, the other five *Daphnia*. In each watch-glass there were twenty drops of clean fresh rain-water. 10.7. To each glass one drop of the 10 c.c. solution of T. & A. was added. 10.8½. The parasitic *Trichodinæ* have fallen off their hosts. 10.9. *Hydra* contracted. *Daphnia* active. 10.10. The parasitic *Trichodinæ* are dead and in disintegration. 10.15. *Hydra* in disintegration, *Daphnia* alive and active—there is absolutely no change apparent in the latter. 10.17. The parasitic *Trichodinæ* are shapeless and disintegrated. 10.18. Each parasitic *Trichodina* is becoming a mere patch of granules. 10.22. *Trichodina* quite disintegrated. 10.24. Some of the examples of *Trichodina* are represented merely by a collection of loose particles. 10.25. *Daphnia* active, heart pulsating. Ectodermal cells of *Hydra* largely macerated off. 10.37. *Hydra* now shapeless and largely disintegrated. Parasitic *Trichodinæ* dissolved. *Daphnia* active and apparently unchanged. Experiment closed. The specimens of *Daphnia* with their ferment-environment were now placed in a beaker, and 50 c.c. of fresh clean rain-water were added. Thirty hours later the *Daphnia* appeared to be all alive and active. Forty-eight hours after the close of the experiment some, at all events, of the *Daphnia* were alive and active. The weather had now become very warm.

XI. *Amœba*. An *Amœba* was placed in a cell along with three drops of clean fresh rain-water and one drop of the 10 c.c. solution of T. & A. This was done at 10.50 A. M. By 10.51 the *Amœba* had been found under the microscope. It was then rounded and its pseudopodia, such as they were, gave it the appearance of a horse-chestnut in its shell. 10.52. *Amœba* sending out pseudopodia. 11 A. M. There are still movements in its interior, and pseudopodia are still present. 11.7. Contraction of contractile vacuole. 11.10. Still moving by means of pseudopodia. 11.17. No pseudopodia. Curious linear wormlike movements. 11.21. Nuclear end contracted, while the other end is still moving in wormlike fashion. 11.28. Appearance tadpole-like. 11.29. Nuclear end a rounded mass with soap-bubble-like ectosarc. 11.30. Dumb-bell-shape with narrow bridge between the two ends. 11.30½. No movements in interior. 11.32. New

blunt process formed at side of larger portion. 11.34. Contents of new process now flowing back into main portion. 11.40. Another blunt process formed, quick movements in its interior. 11.45. Broken into two pieces, of these the one never stirs again, the other moves a little, then rounds up, and remains still. Both dead. Experiment ended.

XII. *Cordylophora lacustris, Carchesium polypinum,* and a Hydrachnid or water-mite. The material of this experiment consisted of two asexual generations, *Cordylophora,* a fresh and brackish water polype, a very fine collection of it, and upon it here and there colonies of the beautiful bell-animalcule, *Carchesium,* and a sexual generation, a water-mite or Hydrachnid. This latter was found in one of the watch-glasses used. In the following experiment the glasses were under observation from 11.15 A.M. until 5 P.M., and 24 hours later than this the glass containing the Hydrachnid was examined, and the water-mite was found to be still alive and active. It had thus lived in a fluid containing these pancreatic ferments for quite 30 hours, while its asexual companions had long ceased to exist, as will be seen. The reagents of the experiment were as follows: The usual 10 c.c. solution of T. & A. was made up. Of this 1 c.c. was further diluted with 4 c.c. of clean fresh rain-water. Four watch-glasses, labeled A, B, C, and D, were taken, and in each, in 20 drops of clean fresh rain-water, specimens of *Cordylophora* and *Carchesium* were placed. 11.15 A.M. Of the 5 c.c. of further diluted ferment-solution there were added to A 2 drops, to B 4 drops, to C 6 drops, and to D 8 drops. Describing, first of all the changes undergone by *Cordylophora*, 11.26 polypes in D contracted. 11.53. In polypes of C queer appearance of tentacles, thread-cells in dissolution. 12.10. Polypes in B contracted. 12.20. Polypes in C disintegrating. 12.35. These latter now much disintegrated. 1 P.M. In A, B, C, and D all the polypes of *Cordylophora* dead and in disintegration. It should be noted that D, although containing more of the ferment-solution than C, had also more polypes of *Cordylophora.* Possibly this, along with the coldness of the day, accounted for the slowness of the action. The Hydrachnid or water-mite in B was observed at the very start of the experiment endeavoring to avoid the attack of a polype of *Cordylophora,* and doing this only with difficulty. An hour later the polype made no attempt to attack the mite, which could now crawl over it with impunity. In this experiment some of the *Carchesium* were still living at 2 P.M., but in the three stronger solutions they were dead and digested by 5 P.M. The action upon *Carchesium* is given in a later experiment (No. XIV.)

XIII. *Planaria lactea,* a sexual generation of a planarian worm. Temperature 16.5° C. 11.28 A.M. A watch-glass, containing 50 drops of clean fresh rain-water and *Planaria,* to which 5 drops of the 10 c.c. dilution of T. & A. were added. All that was noted was a cessation of the tendency to crawl on the glass, and an attempt to get out of the fluid, possibly on account of the glycerin. After the animals had remained for three-quarters of an hour in the fluid, they were removed alive to fresh rain-water. Three hours later they were still alive, but they made no attempts to crawl up the side of the glass.

XIV. *Nais proboscidea* and *Melicerta ringens,* two sexual generations, and *Carchesium polypinum,* an asexual generation. Temperature 15° C. Two watch-glasses were taken, A containing 10 drops of clean fresh rain-water, and B 50 drops, and in each glass specimens of the three animals were placed. At 11.12½ A.M. to each glass one drop of the 10 c.c. dilution of T. & A. was added. By 12.25, some seventy minutes later, in both glasses numerous *Carchesium* were in disintegration, but in both here and there single "polypes" of *Carchesium* were alive and active. The action was not so marked in glass B as in glass A. 1.10 P.M. Practically all the *Carchesium* in A were in disintegration, in B, although all the *Carchesium* were dead, not all the "bells" were freed from their stalks, which were now contracted somewhat spirally. At 12.30 P.M. numerous minute "swarm-spores" (of plants) were observed swimming actively among the débris of the *Carchesium.* On the rotifer, *Melicerta,* no action could be noted. Of the worm, *Nais,* the ferments obviously attacked and dissolved the cuticle. Apparently, owing to this action, at 1.10 P.M. while the one individual was still alive, the other was nearly dead. At 6 P.M. both were dead and in disintegration.

XV. *Nais proboscidea* and *Carchesium polypinum.* The result in the preceding experiment, ending in the death of the *Nais,* led to the conclusion that solutions too strong had been employed in the experiment, and that either the glycerin-menstruum, or the ferment-solution itself, was responsible. Therefore, the experiment upon *Carchesium* and *Nais* was repeated as follows, with still greater dilutions. As will be seen, with this modification the experiment was a complete success. Temperature 16° C. The stock-solution used was the same as in the preceding experiment. Five watch-glasses (A, B, C, D, and E), containing respectively 10, 20, 30, 40, and 50 drops of clean fresh rain-water were taken. In each there were a number of "bells" of *Carchesium* and a worm, *Nais,* and to each, at 11 A.M., one drop of the 10 c.c. ferment-solution was added. Until 3 P.M. no effect upon any of the organisms was observed. At this time the fluids were removed, fresh rain-water given as before, but to each glass five drops of the ferment-solution were added. 5 P.M. In A, while the *Nais* was still alive and active, many of the *Carchesium* were dead and in disintegration. This was confirmed at 6 P.M. and 7 P.M. Next morning at 10 A.M. the experiment was seen to have been decisive. All the *Carchesium* "bells" were dead and in disintegration. All the worms, *Nais,* were alive and active. In the latter no traces of damage could be detected. In A to E the stalks alone represented the former "bells" of *Carchesium,* along with a débris of diatoms. Nine hours later the *Nais* were all still alive and to all appearance unhurt, and just living their ordinary life—*in the fluid containing ferments*—as though nothing had happened. A day later the experiment was stopped, but even the worm *Nais* in A, the glass containing most proportion of ferments, was alive and active. It had been in this solution in rain-water for more than two days.

XVI. *Actinosphærium eichhorni,* a Heliozoan or sun-animalcule. Temperature 16° C. One cubic centimeter of the usual 10 c.c. stock-solution of ferments, freshly prepared, was further diluted with four cubic centimeters of clean fresh rain-water. To *Actinosphærium,* an (asexual) fresh-water Heliozoan, in two drops of clean fresh rain-water, one drop of the further dilution of ferments was added at 10.58 A.M. In less than one minute the long delicate hairlike pseudopodia had their ends bent and somewhat thickened. 11 A.M. The hairlike pseudopodia are nearly all gone, and at

11.2 A.M. they have ceased to exist, and the animal is evidently in disintegration. 11.5 A.M. The animal is in dissolution, and the central capsule is escaping. 11.27 A.M. Shockingly disintegrated. 1.30 P.M. Contents of capsule scattered in fluid. At 11.18 A.M. it is noted that the addition of one drop of the further diluted ferment-solution to a drop of water containing *Actinosphærium* causes *immediate* shrinking and shriveling up of the fine delicate pseudopodia.

XVII. *Stentor caruleus.* Temperature 14° C. The usual stock-dilution of 10 c.c. of the ferments T. & A. was made up. Of this one cubic centimeter was diluted with four cubic centimeters of clean fresh rain-water. Five watch-glasses, each containing a number of *Stentor*, were labeled A, B, C, D, and E. In the order given these contained rain-water as follows: 18, 16, 14, 12, and 10 drops. The bulk of each was made up to 20 drops by additions of the further dilution of the ferments, or 2, 4, 6, 8, and 10 drops of the solution thus diluted. It was calculated out that at the most the glasses would contain the following numbers of tryptic units (Roberts): 3, 6, 9, 12, and 15. The experiment began at 11.30 A.M. 11.40 A.M. *Stentor* in E and D mostly at rest. In C some in movement. 11.41. In B some moving fairly quickly In A the specimens of *Stentor* are moving as though nothing had happened. 11.42. The animals in D and E appear to be in disintegration. The cilia are not obvious. 11.45. The animals in A and B are still in movement. Most of those in D and E are dead. 11.49. In E disintegration is going on rapidly, but in D a water flea, *Daphnia pulex*, is actively moving. This was seen later on, alive and active, 27 minutes after the experiment started. Afterwards it was lost sight of. The animals of *Stentor* in the same watch-glass were killed in ten minutes or less. 11.54. In B many *Stentor* in disintegration, but some still in movement. *Stentor* in C in disintegration, no ciliary motion. 12 noon. In A and B still some movement. 12.3. Movements in B appear to be ceasing, but not in A. 12.4 P.M. Animals in E greatly disintegrated, many algæ freed. 12.18. Heaps of freed algæ in D and E. 12.20. In A still some ciliation, but in many the cilia are working feebly. 12.25. The animals in B are now much disintegrated. 12.32. Slow ciliation in A and all the animals are crowded together. 2 P.M. In A still the same condition of affairs, but only one animal moving cilia. At 7 P.M., when the experiment was closed, there were still some animals of *Stentor* alive in A, but in the four remaining watch-glasses all the specimens of *Stentor* were dead and in disintegration.

My acknowledgments are due to Messrs. Fairchild Bros. & Foster for the two boxes of ampoules of injections of trypsin and of amylopsin used in the experiments. All the organisms employed in the foregoing experiments were supplied by Mr. T. Bolton, Edgbaston, Birmingham. The number of animals experimented upon would have been much greater, had all the organisms he sent survived the transit in summer. Of course, it was only possible to use organisms which were in a healthy active condition. The seventeen experiments hitherto carried out have established the truth of the thesis, that living *asexual* generations of animals are attacked, killed, and their albumins pulled down by solutions of the pancreatic ferments, trypsin and amylopsin (Fairchild), in which *sexual* generations of animals go on living. The following *asexual* generations of animals exhibited the deadly pulling-down action of pancreatic ferments, and thus revealed the dextrorotatory nature of their albumins: *Hydra, Cordylophora, Trichodina, Vorticella, Carchesium, Amœba, Actinosphærium,* and *Stentor*, eight in all.* The beneficent action of trypsin and amylopsin upon *sexual* generations of animals is to me so self-evident, that it has appeared to be almost a work of supererogation to make experiments in this direction. However, for the benefit of the sceptic, the following *sexual* generations of animals continued to live in solutions of these ferments, which proved to have deadly disintegrating effects upon the afore-mentioned *asexual* generations of animals: *Daphnia*, a Hydrachnid or water-mite, crustacean "*nauplii*,"† *Planaria, Nais*, and *Melicerta*, six in all.‡ Zoologically, the experiment (No. X) with *Hydra fusca* and *Daphnia pulex* has special interest. *Daphnia pulex* is a common prey of *Hydra*. It is impossible to keep *Daphnia* living in an aquarium containing *Hydra*. Even the individuals of *Daphnia*, which it does not catch and devour, *Hydra* quickly kills with its stinging cells. More than once I had noted that if a number of the two forms, *Hydra* and *Daphnia*, were associated together in a small aquarium, in the space of twenty-four hours there would be no living Daphnids in the vessel. In experiment X the tables were turned, and in the presence of pancreatic ferments, trypsin and amylopsin, it was *Hydra* which was killed and pulled to pieces, whilst the Daphnids survived. This is possibly the first occasion on which in close association together in nature *Hydra* was impotent to kill its prey, *Daphnia pulex*. Without doubt it is by means of a ferment that *Hydra* kills *Daphnia*. This fact answers by anticipation an objection, which may be raised, that *Daphnia* is protected from the action of trypsin and amylopsin by its chitinous covering. This latter is no protection whatever against the antithesis of trypsin, the ferment produced by the stinging cells of *Hydra*. Indeed, it is not too much to say, that the result of the experiment with *Hydra* and *Daphnia* alone would suffice to establish the existence of two categories of albumins *at least*, laevorotatory and dextrorotatory respectively.

With Emil Fischer I maintain, that "the enzymes are quite especially valuable—as means of recognition of stereochemical differences," and that "of two molecular looking-glass image forms"—in the present case living albumins of animals—"the one is broken up by enzymes under the same conditions under which the other remains intact." His examples were the glucosides; mine the living albumins of certain animal organisms. Two examples were held by him to suffice to establish his theses; for mine more than two are adduced, and, moreover, if shown to be desirable, the number can be increased very considerably. For, in fact, the organisms employed in the actual experiments were but samples, chosen in haphazard fashion, of a large series of microorganisms or developing organisms, all of which—and their name is legion—

**Eight*, without mentioning the "various undetermined flagellate microorganisms" of experiments Nos. IV. and VII.

†Crustacean "*nauplii*" are not "laryæ" or asevual generations. For many years, with the late Geheimrat Prof. Anton Dohrn, I have regarded them as being immature *sexual* generations of Crustacea. Experiment No. V. proved the truth of this.

‡*Six*, without including the "various undetermined 'swarm-spores' of plants" of experiments Nos. VII. and XIV.

would, if identified embryologically as *asexual generations,* exhibit the same phenomena of death and disintegration in the presence of active pancreatic ferments. The *asexual* nature of the organisms experimented upon as such had been decided previously, and upon other than chemical grounds, that is, from developmental and biological data. *Not a single one of the experiments failed to confirm the biological conclusion.*

On the present occasion it is not my intention to examine the bearings of the facts and conclusions upon ordinary zoological problems, for to do so would carry the discussion too far. Possibly, it may now be recognizable, that the heretical preaching of antithetic alternation of generations in the wilderness in past and recent years had its fount in scientific truth. Possibly it may become evident that in some groups of animals, such as sponges, ctenophores, sea-anemones, and corals, as well as in *Hydra* and *Cordylophora,* the sexual generation is not represented except by the forerunners of the sexual products, eggs and sperms. It is, however, the duty of the scientific investigator to draw the conclusions from his observations and experiments, and this I shall now proceed to do in certain interesting and obvious directions. (1) The experiments confirm the truth of the biological and embryological conclusions, that the cycle of animal life, even that of such microorganisms as protozoa,* is an antithetic alternation of asexual and sexual generations, of such a nature that the albumins of the asexual generation (dextrorotatory) are the stereochemical antitheses of those of the other or sexual generation (levorotatory). As I have pointed out elsewhere,[6] the conditions are reversed in plants.† Here it is the *asexual* generation, which possesses levorotatory albumins and dextro-sugars. (2) All such asexual generations of animals, including all malignant tumors, are killed and pulled down in the living state by the action of active solutions of the pancreatic ferments, trypsin and amylopsin. (3) Since "Science is prevision"—to quote the words of Pasteur—and because of certain facts known to me, certain other conclusions may be drawn. As long ago as 1907 (MEDICAL RECORD, February 2), I stated that the pancreatic ferments, trypsin and amylopsin, were the natural means to be adopted for the cure of tuberculosis. This was confirmed in a single case of tuberculosis of the bowel by Dr. Margaret A. Cleaves,[7] and in various forms of surgical tuberculosis by Dr. W. Bätzner.[8] Since the latter has shown that solutions of trypsin do not inhibit the growth of cultures of tubercle bacilli, the favorable result in tuberculosis is seen to be due, as I had long foreseen and foretold, to the use made by the leucocytes of the ferments, trypsin and amylopsin, as weapons of attack. While Dr. Bätzner has observed that three injections of active pancreatic ferments suffice to heal a tubercular abscess, in India Captain F. W. Lambelle, R.A.M.C., using the like Fairchild injections, has found, in a bad case of amœbic dysentery with abscesses in lungs and liver, that the like number of injections (three) result in the clearing-away of all the *Amœbæ,* and the healing of the abscess. From these facts, from the experiments, and, more especially, from the whole course and tenor of my researches during the past twenty-four years, the following additional conclusions find their scientific warrant.

Since the organisms underlying the chief tropical diseases, such as malignant malaria, trypanosomiasis, sleeping sickness, yellow fever, relapsing fever, kala-azar, etc., are, so far as these attack human beings, asexual generations, it follows that the natural means of destroying the organisms of such tropical diseases and of curing the patients, are the use *in combination* of the powerful pancreatic ferments, trypsin and amylopsin, as represented by the "1912" Fairchild injections.

A further step may, indeed, be taken. Since such tropical disorders due to parasitic microorganisms of an asexual nature and tuberculosis are amenable, since the organisms of such nourish themselves, increase, and multiply at the expense of the living human organism with its characteristic levorotatory albumins, and—last not least—because the greater exceeds the less, all infectious diseases, due to parasitic organisms of an asexual nature, all which possess dextrorotatory albumins, such as pyemia, smallpox, scarlet fever, pneumonia, leprosy, Asiatic cholera, and others of a similar nature, must be, and are, curable naturally by the all-powerful ferments, trypsin and amylopsin, in combination.

In order to grasp the bearings of the facts of the present writing upon problems concerning diseases, in which unicellular organisms, bacilli, etc., play a leading part, it is needful to know something of the biology of digestion and of the relationships of extra- and intracellular ferments. In the unicellular animals or protozoa, which, so far as disease is concerned, manifest themselves as asexual generations, in the asexual generations of the higher animals, in the mammalian trophoblast, and in its pathological representative any malignant tumor or cancer, digestion is intracellular, and by means of ferments acting within and upon the surface of the cell. In the sexual generations, man for example, a differentiation has taken place, of such a nature that the production of the characteristic digestive ferments has been assigned to a certain portion of the alimentary canal, and these ferments act in an extracellular fashion. Not only have most of the body-cells lost the power, if they ever at any past time possessed it, of producing trypsin and amylopsin, but a further division of labor has taken place in the original single digestive gland, its ferment-producing properties have been localized in a part of the original structure, and this part we term the pancreas-gland, while its other functions have been reserved for the portion of it which we term the liver. I am not concerned here with the question of the production of ferments by and in the vertebrate liver. But any tryptic and amylolytic ferments contained in the liver are almost certainly formed in the pancreas-gland. The aspect of the matter concerning us here is this: owing to such

**Antithetic Alternation of Generations in Protozoa.* In "The Annals of Botany," V. 9, 1895, pp. 446-447 and 468, in the course of a paper dealing with "The Phenomena of Reproduction in Animals and Plants," it will be seen that I recognized, and postulated, the occurrence of antithetic alternation in the life-cycles of the unicellular organisms. In not the least brilliant of his memoirs this was first demonstrated, in the case of *Coccidium schubergi,* by that zoological genius, the late Fritz Schaudinn (vide Schaudinn, Fritz—Untersuchungen über den Generationswechsel bei Coccidien, in: Zool. Jahrb., Abt. f. Anat., V. 13, 1900, p. 197).

†Therefore, in experiments Nos. VII and XIV, unlike the *asexual* generations of animals, such as the "various undetermined flagellate microorganisms" of experiments Nos. IV and VII, the "various undetermined 'swarm-spores' of plants" were not killed and disintegrated, but continued to live, in the presence of active pancreatic ferments, trypsin, and amylopsin. These "swarm-spores" probably belonged to the Confervoid division of the green Algæ, such as *Ulothrix.*

division of labor the body-cells, in giving up any earlier power possessed by them of forming trypsin and amylopsin, are placed more or less at the mercy of organisms, such as some protozoa, bacilli, etc., which by their ravages induce disease. The ferments, produced by these, being the stereochemical antitheses of those of the normal human body, when given the chance, are in this way enabled to attack the body-cells, which have as their sole immediate protectors the cells termed leucocytes. The leucocytes form the first and only real line of defense against the attacks of such microorganisms. It was Metchnikoff[9] who first insisted on these protective powers of the leucocytes. Notoriously, in many forms of parasitic disease, produced by a microorganism, a bacillus, or asexual generation, such as cancer, the leucocytes are quite unable to cope with the foe. But increasing evidences go to demonstrate that, if provided with pancreatic ferments as additional weapons of attack, the leucocytes can become highly efficient agents against such onslaughts. Moreover, it must not be forgotten that the ferments are bodies, which do not, to any extent at all events, diffuse or pass through the walls of the alimentary canal and circulate in the blood.

From the point of view of practice it may suffice to note the following: The introduction of pancreatic ferments, such as the new Fairchild preparations, into the blood is, as others have demonstrated, a perfectly harmless procedure. In such afflictions as sleeping sickness, malignant malaria, tuberculosis, etc., the organisms concerned are enabled to succeed in their attacks, because of the absence of the naturally protecting ferments, trypsin and amylopsin, but, given these circulating in the blood at the point of attack, the body—often, as in tuberculosis, aided by the leucocytes—is placed in a position not merely to resist the attack, but to defeat it utterly.

It is a long time since 1860, and the fundamental discoveries of Pasteur,[10] published in that year, discoveries relating to what he termed "enantiomorphism," have had a curious subsequent history. While, on the one hand, it would, perhaps, not be too much to say, that their influence upon the progress of chemistry had been unbounded, their import in physiology and allied sciences, dealing with the problems of living things, such as embryology, zoology, and botany, would not appear to have been recognized hitherto. It is scarcely credible now, that so long ago as 1860 Pasteur said, "I have, in fact, set up a theory of molecular asymmetry, one of the most important and wholly surprising chapters of science, which opens up a new, distant, but definite, horizon for physiology."[10] While admiration of Pasteur's "prevision"—to use his own word—must be expressed, one cannot refrain from astonishment, that more than fifty years, at all events, should have elapsed without a fulfilment of his prophecy.

Applying now his discoveries, the later ones of Emil Fischer, and the facts here recorded, to the problems of living things, clearly there is a general principle of far-reaching import behind the whole. This is, that the microorganisms, bacilli, etc., of disease are, of necessity, composed of compounds which are stereochemical antitheses of those making up the normal human body, and that, when compared similarly with the pancreatic ferments, the like is true of the ferments, by means of which they effect their ends. Only by means of such antithetic or opposite characters of compounds and of ferments produced by them could such disease-inducing organisms bring about their ravages.

It follows naturally, irresistibly, and incontrovertibly, that the rational ways and means of meeting and coping with such ravages are the employment of the ferments produced by the organisms, to wit, mankind, who are the victims, and of these by far the most potent are the pancreatic enzymes, trypsin and amylopsin. Indeed, the final outcome of the present adventure is to demonstrate once again beyond effective contradiction, that the pancreatic ferments, trypsin and amylopsin, *in combination* are the most powerful agents in the whole range of organic nature.

By the researches of earlier years antithetic alternation of generations as *the law* of the developmental cycle of animal life had been placed upon a firm basis of observation. With the facts now recorded a beginning has been made in supplying this law of antithetic alternation of generations with a foundation in stereochemistry.

Upon what foundation do the current orthodox conceptions of the nature of the above-mentioned diseases rest? Certainly as little upon a chemical as upon a biological basis. The line of work I took up four and twenty years ago may have been —may even now be—"heretical," regarded in the light of common beliefs then and now current. But the error was, and is, in the current beliefs and theories, and *not* in the "true theories" or general principles, to which patient research during these years has led me irresistibly. For, as Pasteur well said, "The characteristic of erroneous theories is, that they are never able to present new facts; and every time a fact of this nature is discovered, in order to take it into account, they are obliged to graft a new hypothesis upon the old ones. The characteristic of true theories, on the contrary, is of being the expression of the facts themselves, of being commanded and dominated by them, of being able to foresee new facts certainly, because these by their nature are linked up with the former—in a word, the characteristic of these theories is fecundity."[11]

## THE ACTION AND ADMINISTRATION OF CROTALIN IN PULMONARY CONSUMPTION AND IN EPILEPSY.

By THOMAS J. MAYS, M.D.,

PHILADELPHIA., PA.

MEDICAL DIRECTOR OF PHILADELPHIA CHEST AND THROAT CLINIC.

That crotalin is a powerful two-edged instrument, and that its practical worth, like that of any other therapeutic agent, depends altogether on a proper knowledge of its active mechanism and on a proper method of administration, are obvious propositions.

The action of crotalin as a whole is fairly well understood, and very little good will come out of a discussion of its active principles until more is known of the constitutent parts of bodies belonging to this class of agents. All that is known concerning the chemical composition of snake venoms at the present time, according to Dr. Armstrong, is that they have the following percentage composition: Carbon, 45.76; nitrogen, 14.30; hydrogen, 6.60, and sulphur, 2.50; yet this throws very little or no light on the nature and constitution of the protein bodies to which venoms are supposed to owe their physiological properties.

Pharmacologically, crotalin stands in close relation to the cyanide group. In fact, after the writer had acquired an experimental knowledge of the action of snake venoms, one of the incentives which led him to investigate the clinical property of this drug was the close analogy of its action to that of this group of agents, and since March, 1908, he has been engaged in studying its application to the diseases with which this article deals. In its rapacious activity, its powerful affinity for the important nerve centers of respiration and muscular coordination, its power to disorganize the blood, and in its mode of producing death through respiratory paralysis and convulsion, it presents an almost exact, although less active, counterpart of the lethal effects of hydrocyanic acid.

Most all experimental observers agree that in dogs, rabbits, cats, fowls, and frogs, snake venom causes death through convulsions and paralysis of respiration; that, as a rule, the respiratory center is destroyed before the convulsive center, provided the venom is administered subcutaneously; that the reverse is true when the venom is inflicted by a bite of the animal; that cobra venom destroys the respiratory functions very quickly; that daboia venom is more actively poisonous than cobra venom; that rattlesnake venom is far less poisonous than either cobra or daboia venom; that bloody diarrhea and other bloody discharges are frequent concomitants in animals that are bitten by daboia snakes, but are not often present when daboia poison is given subcutaneously, and are practically absent in cobra or crotalin poisoning, except late in the process of intoxication, and that the activity of cobra poison is impaired when heated, and destroyed by being heated beyond the boiling point, and crotalin venom becomes inert when heated to 80° and 85° C.

One of the most distinguished observers and experimenters on snake venom, Dr. A. J. Wall,[1] states that the action of cobra venom, although more energetic, bears an analogy to that of crotalin, or rattlesnake venom, viz., a feeling of intoxication, drooping of eyelids, loss of power in legs and arms, staggering gait, inability to walk or stand without support, profuse salivation, paralysis of tongue and larynx, embarrassed breathing, inability to swallow, general paralysis, twitching in limbs, lessening of respiration rate, and finally arrest of breathing, after which the heart ceases to beat.

This author draws a very vivid and very significant comparison between the symptoms of cobra poisoning and those of the disease known as glossopharyngeal paralysis—associating both processes with paralysis of the vagus root, of the spinal accessory, and of the hypoglossal nerve, in which he uses the following language: "In both diseases the respiration becomes feebler and feebler, and the victim at last dies suffocated. In other words, the paralyzing poison in one case and the lesion in the other have invaded the respiratory nucleus so near to the center which they have already destroyed, and have thus rendered the respiratory act difficult and at last impossible; and, though no doubt other parts of the nervous system suffer, it is evident that cobra poison has a specal affinity for acting on the respiratory center and those other ganglia allied to it in the medulla oblongata which are in connection with the vagus, the spinal accessory and the hypoglossal nerves, and that it is directly to this destructive action that we have to attribute death in most cases of cobra poisoning."

In regard to the therapeutic efficacy of crotalin in pulmonary diseases, it may be said that, in the writer's judgment, this lies primarily in its undoubted power of influencing the respiratory center and its outgoing pulmonary nerve fibers; and, secondarily, by its general action on the nervous system, in minimum and medium doses. In fact, it is a therapeutic principle which knows no variance, that when a drug force manifests a selective pathological action on any tract or tissue of the animal body in maximum doses it will exercise a stimulating and supporting influence on the same tract or tissue in minimum and medium doses.

*Administration of Crotalin in Pulmonary Consumption.*—When crotalin was first administered hypodermically by the writer, it was quite a natural expectation that its primary mode of introducton, although this demonstrated its positive efficacy as a clinical agent, was open to improvement, and that time and concentrated study were requisite to bring about its very best clinical value. Indeed, it was with the hope of stimulating further research in this direction that the writer's preliminary observations were first published on this subject in 1908,[2] and there is reason for believing that this hope was not altogether misplaced.

The Arm Method.—The back of the arm was the method which was first selected for the hypodermic injection of crotalin, although subsequent experience has shown that there is no special reason why other points are not equally suitable. This

site was chosen for the reason that no attempt had ever been made to throw this powerful poison directly into the human circulation by means of the hypodermic needle, except by the fangs of the snake, and it was, therefore, deemed wise to remain as far as possible from the central organs of the body in case of any unlooked for emergency.

The hypodermic dose of crotalin ranges from gr. 1/200 to gr. 1/50, or more. It is advisable to begin with gr. 1/200 or even a smaller amount, and gradually increase to gr. 1/50, or more. It will be found that a partial immunity is established in time, and that a larger dose is required to obtain the same effect that a small dose produced at the outset. Chronic cases, especially of phthisis, bear larger doses in the beginning of treatment than diseases of a more acute character.

The following formula has been employed in making a suitable solution for hypodermic purposes; although hypodermic tablets of the same strength are also manufactured:

℞ Crotalini, 1 gr.
Glycerini 100 ♏,
Aqua destil. 400 ♏.

M. 5 minims of this solution represent gr. 1/100, and 2½ minims represent gr. 1/200 of crotalin.

The immediate local effect of a crotalin injection consists of a burning, stinging pain at the seat of injection, often radiating to the fingers or to the elbow or shoulder. The pain is not severe, and is of short duration. Considerable edematous swelling may occasionally occur around the injected spot, but neither the pain nor the swelling becomes very marked. If these symptoms should become excessive, the constant application of a saturated solution of magnesium sulphate will soon bring relief.

*The Neck Method.*—The neck method was resorted to, chiefly for the purpose of influencing the nerve supply of the larynx and lungs in cases of laryngeal tuberculosis, by introducing the crotalin directly over the course of the vagi. This deduction was made from the finding that in other affections, like lumbago and sciatica, for example, crotalin brings relief quicker when it is injected over the seat of pain in the back, or over the course of the nerves in the legs, than when given in the arm.

In this method the needle puncture is made immediately over or slightly behind the pulsating carotid artery, in the region of the neck, in a line between near the angle of the lower jaw and the clavicle, and nearer the latter than the former point. In order to avoid puncturing the carotid artery or its neighboring jugular vein, it is important to pinch up the skin between the thumb and the forefinger of the left hand and introduce the needle just under the elevated skin. The size of the dose is smaller than in case of the arm injection, varying from gr. 1/400 to gr. 1/100, given once or twice a week, and on alternate sides of the neck.

*The Intravenous Method.*—This method has been tested in a large number of cases, but has nothing to recommend it over the arm and neck methods. In fact, it has decided drawbacks, inasmuch as in the case of the intravenous infusion of other substances, in which the writer has had a large experience, it frequently calls forth a violent reaction, consisting of rigors, fever, and sweats, from which the patients rally with difficulty, and from which they suffer permanent impairment.

*The Intrathoracic Method.*—All previous experience with the arm and neck methods showed conclusively that crotalin possessed the marked power of favorably modifying the course and condition of pulmonary consumption, not only in its early, but also in its later stages. It was, therefore, believed that its direct injection through the thoracic walls into lung cavities might enlarge the scope of its usefulness.

Notwithstanding these apparent advantages, it became an entirely different undertaking when it was contemplated to throw this powerful agent into a highly vascular and sensitive organ like the lungs, and it must be confessed that the first venture of this kind was attended by considerable fear and anxiety. This sense of danger was partly mitigated at least by the assurance that in a lung cavity the drug would come in contact with a surface that is more or less indurated, bathed in, and accustomed to the influence of acrid exudative material, and is possessed with less vascular activity than normal lung structure. Experience determined, however, that so far as the injection of cavities was concerned, this fear was practically groundless, for beyond the primary temporary local discomfort which it causes in the chest, no constitutional symptoms of any kind developed. Indeed, when one recalls the pain and disturbance in the chest which is occasioned by the intrapulmonary injection of iodine, potassium permanganate, mercury, carbolic acid, protargol, etc., it seems remarkable that a substance like crotalin may be thrown into an extremely sensitive tissue like the lungs without calling forth more of a reaction than a slight temporary cough, or a feeling of soreness, presently to be followed by a sedative action on the essential symptoms of the disease, is good evidence that it is not markedly offensive to the body.

The dose of crotalin for intrathoracic injections varies from gr. 1/800 to gr. 1/200, and for the first few doses it is advisable to use the smaller amount.

Before the injection is made, it is very important to outline the cavity and to introduce the needle directly into this area and empty its contents there. Previous to the puncture the patient must be instructed to take a deep breath and to hold the lung fully inflated until the injection is completed, and for a short time after the needle is withdrawn to take very short and superficial breaths. To facilitate a safe injection, press the left index finger firmly into the middle of the selected intercostal space and make the puncture of the needle gently, though quickly, at the middle point of the finger tip. If this advice is carefully followed there is no danger of striking the edge of a rib or a blood vessel. The dimensions of the heart must be carefully mapped out in order to avoid puncturing this organ. In connection with this, it is well to remember that in left-sided lung cavities of some duration the heart is sometimes forced or drawn toward the left.

The common hypodermic syringe, with an inch and a half or two-inch needle, of somewhat larger caliber than the ordinary hypodermic needle, answers every practical purpose, except when it is desired to enter a deep cavity, or a bronchiectasy. The injections are to be repeated every five or six days.

*The Nebulization Method.*—The easiest and perhaps the most effective way of administering crotalin in chest affections is by its direct introduction into the lungs through the respiratory passages in

the form of vapor. Over a year ago the writer began to use this method, but in doses which proved to be somewhat too small, although they were not wholly devoid of good effects. Subsequent experience demonstrated, however, that an increased dose of crotalin given in this manner produced much better results.

The preparation of a solution of crotalin for vaporization requires some care and patience. When rubbed up thoroughly, as it must be, with liquid petrolatum, it forms a tolerably fair solution, or suspension, in the proportion of one to one-hundredth part, *i.e.* 1 minim of oil will take up 1/100 grain of crotalin. This solution is vaporized by a De Vilbiss nebulizer, either by means of compressed air coming from a compressed air tank, which is by far preferable, or from the compressed bulb of a hand-nebulizer, and introduced through the nasal passages. The vapor is inhaled to the full respiratory capacity during each inspiration, and is retained in the lungs as long as possible and then exhaled. After a short interval another inhalation is taken, and this is repeated until from fifteen to twenty or more inhalations are taken at each sitting. This procedure is repeated every three or four hours during the day, and it is believed that if the vapor is economically administered in this way, from 1/100 to 1/50 of a grain of crotalin is absorbed by the respiratory passage in twenty-four hours. In the beginning it is advisable to allow the patient to take only six or eight deep inhalations at one sitting, until he is fully accustomed to the operation. Whether the above given dose is large enough for all practical purposes, or whether a larger one is required to bring out the best effects of crotalin when given according to this method, remains to be fully developed by future experience.

The formula which is employed in preparing the solution is as follows, and this should be made fresh every month or six weeks:

℞ Crotalini 4 gr.,
Liquid. petrolati 400 minims.
M. Rub well together in mortar. Sig. Use as an inhalant. Keep in cool place, and shake well before using.

It may be said that the immediate effects of the inhalation of crotalin vapor are good. Improvement follows in the cough, expectoration, blood-spitting, fever, chills, night-sweats, pain in the chest, hoarseness, weakness of voice, laryngeal pain, difficult swallowing, appetite, well-being, and general strength, and at the same time is a marked betterment in the physical signs.[3]

Comparison of Different Methods.—There can be no question in the mind of anyone who has had practical experience with the administration of crotalin in the treatment of respiratory diseases that, whether given under the skin with the needle, into lung cavities through the chest walls, intravenously, or by inhalation of its vapor, it is uniformly followed by favorable results in the great majority of cases. Experience has shown, however, that there is a difference in their adaptability and usefulness. The arm injection was the first method that was employed, but it is sometimes objected to as being painful and as exciting discomfort and swelling of the arm, but none of these are serious drawbacks, and are generally regarded as trivial incidents. The intravenous method gives no superior results to the arm injections, besides being liable to a serious and detrimental reaction. The intrathoracic method is only applicable in cavity cases and is a delicate operation to perform, but is almost invariably followed by good results.

It is probable that a combination of the inhalation and the arm injection methods produce the most efficient practical results in the majority of cases, so far as the writer's experience extends. Whether this will be superseded by a more serviceable method of administration remains to be decided by future clinical investigation.

One thing may be stated with a measurable degree of certainty concerning the preferable mode of applying crotalin in consumption, viz., that that method is the best which brings it in direct contact with the foci of disease. It is obvious, therefore, that the inhalation and the arm injection methods make a very useful combination —the former for the local effect, and the latter for a general effect on the nervous system.

*Crotalin in Epilepsy.*—That crotalin is an efficient factor in the alleviation of epilepsy seems to have been shown by the work of others, as well as by that of the writer.

Before applying the principle of crotalin action to epilepsy, as it is viewed by the writer, it is proper to add a few thoughts on the essenial nature of this disease.

Whatever its cause may be, it must be admitted that epilepsy is fundamentally a nervous affection, and that one of its most prominent and active manifestations consists in a disturbance of the regulating center of muscular motion, resulting thereby in an irregular and unbridled contraction of the general voluntary muscular system. Whether the original impulse of this originates in the cortex or in the periphery matters not, so long as it is absolutely true that no genuine and complete seizure can occur without implicating the muscular coordinating center in the oblongata, which is also known as the convulsive center. In other words, while irritation of the brain cortex, or of an extremity, may initiate a seizure, the course pursued by an impulse so generated eventually involves the controlling center of muscular motion in all fully developed attacks. This center being in close proximity to those which control respiration, circulation, swallowing, vomiting, etc., these also become implicated, and as a result we have embarrassed and stertorous breathing, accelerated heart action, salivation, vomiting, etc., symptoms which we know accompany the convulsive process of epilepsy.

Moreover, epilepsy is devoid of any characteristic organic change in the body, and, therefore, belongs to those diseases which are called functional. There are more things than visible marks or scratches on the cadaver that are to be taken into consideration when we come to estimate the true nature of disease processes. Functional diseases like palpitation and irregular heart action, as well as tachycardia and bradycardia, are affections of no mean order, but are just as real as those which bear the imprint of organic change.

Where is the practitioner who has not witnessed the abatement of irregular cardiac action under the benign influence of strychnine, when this agent was given for effect? In all probability this did not happen when it was administered in 1/100 or 1/60 grain doses, but in the largest possible tolerated doses, the size of which depended on individual susceptibility to the drug, which may be safely conjectured as being somewhere between 1/20 and 1/40 of a grain given three times a day.

Disclaiming any effort to place epilepsy and irregular cardiac action on the same pedestal, so far as their severity and gravity are concerned, it may still be maintained that it is not beyond the range of possibility for crotalin, which has a special elective action on the voluntary muscular coordinating center, to stimulate and to enhance the functional power of this center sufficiently to antagonize the wild and riotous contraction of the general muscular system, in a manner similar to that which is exercised by strychnine on the irregular action of the heart. In both instances the unbridled contraction of the heart in palpitation and the licentious distortion of the muscular system in epilepsy are, in essence, mere manifestations of a paralyzed control of nerve centers which preside over the movements of these respective organs.

It is fairly well ascertained that strychnine possesses no direct influence on muscular contractility, but that it has the power of elevating the function of the cardiac center to a point where it is enabled to resume the power of originating and of sending out impulses capable of exciting a regularity of cardiac contraction, which it is not able to do in the absence of strychnine.

Method of Administration.—In order to secure the full beneficial effects of crotalin, it will be found that the mode of giving it is of considerable importance. Its failure has been demonstrated in several cases in which too large doses had been given in the early stage of the treatment. Great caution is necessary, therefore, at the very outset, that minimum doses are administered, and if this is not borne in mind it will frequently be followed by discouragement. A minimum quantity, varying according to age, from 1/200 to 1/500 of a grain should be given at the beginning of treatment, and this should be slowly and gradually increased until a slight degree of immunity is established. For example, in a boy of fourteen or fifteen years old, begin with 1/200 grain or less in the forearm every third or fourth day, for a period of about two or three weeks, then give 1/150 grain for a similar length of time, and gradually work your way up in this manner until you reach 1/100 grain. After this point is reached, or even before, give the latter quantity in equally divided doses in each forearm. The 1/100-grain dose is given for a month or two, every six or seven days, after which give 1/150 or 1/100 grain each forearm once a week. This dose may be increased to 1/75 or 1/50 grain in each forearm, once a week, but these doses are not frequently necessary, except in the case of patients who become readily immune to the drug. If at any time during the treatment there should be shown a marked degree of immunity to it by the patient, *i.e.* if very little local reaction, or hardly any, should occur at the seat of injection, the dose should be increased at once. After giving it for a long while, say a year and a half or two years once a week or ten days, it is advisable to reduce the dose to 1/100 or 1/200 grain.

The crotalin solution to be used for hypodermic injection in these cases, and which should be made fresh every four or five weeks, is prepared in accordance with the formula given above, and the back of the arm has been selected for the site of injection, although there is no reason why any other spot should not do equally well.

No special antiseptic precaution is necessary to ward off any untoward effects. For some reason (probably on account of its animal source) the human system does not seem to be particularly irritated by or to take unkindly to this poison. For in more than six thousand injections the writer has failed to meet a single serious complication of any kind.

In regard to the length of time which is required before crotalin is able to make a well-defined impression on the seizures in any particular case, it may be said that this varies in different individuals. Sometimes the attacks will be interrupted after two or three doses have been administered, while in other cases, especially in those in which the minor attacks predominate most largely, it seems to require a longer time to bring about a decided effect. At any rate, if the attacks do not abate at once, or as soon as they were expected to, continue the injections as directed above, and in the great majority of cases the beneficial effects will manifest themselves in a reasonable time.

As to how long crotalin will have to be continued before there is a permanent cessation of the attacks, not a sufficient length of time of its use has elapsed to form a definite opinion, especially not, if it is true, as some high authorities maintain, that no case of epilepsy can be called cured until the attacks have been checked for a period of five or six years.

One of the most aggravated cases treated by the writer had one hundred and sixty major attacks in one month before the crotalin was given, but the seizures finally yielded to the influence of the latter, and have not returned for a period of a year and three months. It is, therefore, quite certain that not until the drug has been used more extensively and for a long time, and not until a sufficient amount of clinical material has been collected, will anyone be in a position to give a definite opinion on these points. Judging its effects, however, from the experience of others and that of the writer, who have given it persistently for several years, there is little, if any, doubt as to its utility, and that in regard to permanency it will, in all probability, be able to hold its own.

Note.—Since the preparation of this article, the writer has been surprised to learn that crotalin is dispensed for hypodermic purposes in ampules, at an exorbitant and a practically prohibitive price. He, therefore, wishes to add that among the many thousands of injections which he has given in the last five years, he has never encountered an abscess, or any other serious mishap, and is, therefore, unable to see any good reason why the exorbitant high-priced ampule should be substituted for the comparatively inexpensive solution as given above.

3. During the last year and a half Dr. Isaac Barton, of this city, has been using intralaryngeal and intratracheal injections of crotalin solutions with very good results. The writer has had the opportunity of witnessing the favorable effects of the administration of this drug in this way in a number of instances. Dr. Arthur C. Wolfe, of Ridley Park, Pa., has treated a number of cases of laryngeal tuberculosis by injecting small doses of crotalin directly into the mucous surface of the larynx and its immediate surroundings, and, it is claimed, with favorable results.

# THE MENACE OF THE "RECOVERED" INSANE.

By EDWARD HUNTINGTON WILLIAMS, M.D.,
MONTCLAIR, N. J.
FORMERLY OF THE NEW YORK STATE HOSPITAL SERVICE,
AND
JAMES SPENCER BROWN, M.D.,
MONTCLAIR, N. J.
SURGEON-IN-CHIEF MOUNTAINSIDE HOSPITAL.

EVERY patient discharged as "recovered" from an insane hospital is a menace to the community. This menace may be direct or indirect, local or general; or it may be all of these. Directly and locally the menace is through the tendency of the disease to recur; indirectly and generally by the probability that such a case will beget offspring, and thus with deadly certainty transmit the neuropathic make-up.

Consider, for example, the case of a young man of thirty who has "recovered" from an attack of manic depressive and resumed his accustomed place in the circles of his community. Let us assume that he remains in apparently normal health for the rest of his life. Under such circumstances he will almost certainly beget offspring, legitimately or otherwise. If illegitimately the effect upon future generations can only be estimated by a personal knowledge of the man's sexual intensity. If legitimately, we can predetermine the certain effects with scientific—almost mathematical—accuracy, thanks to the work of the Austrian celibate, Mendel. In either case the community will suffer, in our own generation, or the next.

For even if this man be fortunate enough to marry a normal woman of pure normal ancestry, and all his children be normal, a certain number of his children's children will not be. So that his grandchildren—and, incidentally, your grandchildren and mine—will inherit a legacy requiring the care of a certain number of dependent defectives.

If he is less fortunate and marries a woman who is herself normal, but who inherits a neuropathic taint even from one grandparent, half his children will be neuropathic, and half will be normal but capable of transmitting the neuropathic make-up to their progeny. And in that case a burden will be placed upon our children as well as upon our grandchildren.

If he is most unfortunate, and chooses for his mate a woman who is neuropathic, all their children will be neuropathic. And in that event not only will our children and our grandchildren be burdened, but we ourselves will be called upon to help support a certain number of insane, epileptics, alcoholics, or other defectives.

It is not a covetable heritage. The population and the difficulty in procuring food are both steadily increasing: one condition is undoubtedly dependent upon the other. Meanwhile the number of insane dependents seem to be increasing twice as fast as the population. If we find no means of correcting these conditions the ultimate result is obvious and appalling, and may well cause thoughtful persons to question the desirability of such promiscuous increase in population as taught by creeds, and shouted by certain politicians.

Such views are based on the assumption that a blessing of yesterday is a blessing to-day and will be a blessing to-morrow. But economic conditions that existed in the past—even fifty years ago—do not prevail at present. Applied science has prolonged the average term of human life without correspondingly increasing the means of supporting it. Nature's laboratory, not the laboratory of the scientist, is still the only source of our food supply; and the productive capacity of this laboratory is being sorely taxed.

Before the intervention of science—only yesterday, as it were—famine, pestilence, and war, so depleted the population that there were more land than tillers. Food that could be had for the sowing on land that could be had for the taking, was cheap. And when this land near at hand became crowded there was more to be had a little farther on. At that time there were frontiers to be conquered as well as cultivated, and men were needed for both. But all this is changed. Even in America the free lands are gone; and the rate of production on the available land is not keeping pace with the increase of population. Thus in 1909 there was an increase of 21 per cent. in the population of the United States over that of 1899; but there was an increase of only 1.7 per cent. in the entire crop of cereals. Stated otherwise, there was a shortage of full ten bushels for each man, woman, and child in the country.

At the same time there is a corresponding decrease in the number of meat-producing animals per capita. The aggregate decrease in hogs, sheep, and meat-cattle between 1900 and 1910 was 23,499,073 individuals. Thus there are sixteen million more human beings to be fed; twenty-three million fewer meat-supplying animas to feed them.

Coincident with such figures we are confronted by the fact that at least one per cent. of our population is insane or congenitally defective (non-producers), and their numbers increasing "at a rate which is about two times as great as the rate of increase of the general population." Such a condition presents a serious problem to-day, and unless radically changed, will menace us to-morrow. What are the available means of combating it?

Our efforts to cure insanity, once it has fully developed, have thus far proved practically fruitless. "Very few cases indeed recover permanently," says Rosanoff. "Further, it must be pointed out that treatment may be palliative but does not materially affect the prognosis, and that in a given case the course and termination will depend upon the nature of the disorder and may be predicted without reference to the management of the case." In other words we have snatched the insane from filth and suffering and made their condition one of cleanliness and comfort, without finding a means of curing them or changing the inevitable course of their disease. Obviously, then, we should seek other remedies. And the remedy that naturally suggests itself is that of preventing the propagation of neuropathic progeny—universal quarantine against the psychosis plague.

One of the most important steps toward accomplishing this must be along educational lines. Such organizations as the National Committee for Mental Hygiene are doing valuable work in this field and cannot be too highly commended and supported. But we have reason to fear, from the discouraging results in other allied fields, that education alone will prove a distressingly slow process. The existing opposition to vaccination among seemingly intelligent people is a case in point. And we certainly cannot hope that a man with this non-receptive type of mind will deny himself the right to marry the girl he loves simply because he knows that one of his or her parents were insane. More-

over, the exact mental status of four parents cannot always be determined. But wo do know the mental status of the individuals who have been pronounced insane officially, and by one means or another we should try to prevent the perpetuation of their defective make-up.

A radical method that naturally suggests itself is that of passing and enforcing laws preventing the marriage of any person once officially declared insane. But obviously such laws would not be effective. They could indeed be nominally enforced, just as in the case of the law against bigamy. But as in the case of this law, they would not prevent illicit sexual intercourse. So that, instead of curtailing the dissemination of the neuropathic germ plasm, such a law might result in scattering it broadcast instead of confining it to a single family.

It has been suggested that laws be enacted allowing recovered insane persons to marry, but forbidding them to propagate children *until after five years of married life*. We could pass such an absurd suggestion without comment were it not for the fact that it is being promulgated by persons whose word carries weight. Yet there are two patent and vital objections to it: (1) It is impracticable; (2) it would not alter ultimate results if it were so; the power of transmitting the neuropathic make-up is not lost in five years, or during the sexual lifetime of the individual. As to the probability of children being propagated during those first five years, we may judge by the results of married life among normal individuals. For every physician knows that during those first five years, both man and wife, in a large majority of instances, try to avoid propagating children by every method that can be gleaned from more experienced friends, relatives, and gossiping neighbors. Yet conception usually takes place during that period. Such being the case we certainly cannot expect that the unfortunate neuropath will succeed where his normal brother fails.

Compulsory segregation in permanent psychopathic colonies offers a possible solution of the problem. But this would be, in effect, to increase the scope and dimensions of our already top-heavy asylum systems so as to make them permanent residences for committed persons, with added marital privileges. At best such a method would only focalize, without correcting, the evil.

Sterilization, by vasectomy in the male and division of the fallopian tubes in the female, offers an effective, and possibly the most practical method of protecting our own and future generations from the increasing number of neuropaths. Both are simple operations and are attended by practically no mortality when performed by competent surgeons. And if laws were enacted whereby the recovered insane person might elect whether he remained unmarried or submit to sterilization, they would probably be reasonably effective, and at the same time quite as humane as the existing laws for controlling the insane.

That such a law would impose hardship on the unfortunate neuropath cannot be questioned. Undoubtedly the greatest of these would be the denial of the right to "have children comfort his declining years." But if, through a campaign of education, the psychopath (and the general public) could be shown that such children were likely to be anything but a "comfort"—a humiliating drag, indeed, as regarded at present—his attitude toward the desirability of progeny might be corrected, particularly as his sexual pleasures and instincts need not be interfered with.

A certain number of psychopaths would prefer to remain unmarried, and satisfy their sexual craving illicitly, rather than submit to sterilization. But this would be almost exclusively among the males; for even a vicious woman usually prefers to hide her immorality under the cloak of matrimony. So that, in practical application, a law for sterilization ought to be quite as effective as most other laws.

There are of course serious obstacles to be overcome before such a law could be enacted or executed. The legal mind obtrudes the question of personal rights of the individual. But this objection is answered by the present legal attitude toward insanity. Certainly it is no more an infringement of personal rights to forbid marriage without previous sterilization to a person whose insanity is quiescent than to imprison that person when the disease becomes active. Moreover, we have the precedent—the legal touchstone—of laws permitting the sterilization of criminal neuropaths in several states.

A more formidable opposition comes from certain churchmen, who object to sterilization on moral grounds. The same objection was raised against etherization half a century ago, the opposition of conservatism to progress. But it is reasonable to believe that a campaign of enlightenment would remove this objection to sterilization as it did the opposition to anesthesia. It is a matter of being able to present facts as well as theories.

Fortunately we are now in a position to do this. Practical observations of the working of Mendel's laws have shown us that the neuropathic make-up is transmitted along definite lines, and can therefore be combated with certainty. We know that normality is a dominant trait that breeds true; that normal human beings with normal ancestry will beget normal offspring—a thing we could only surmise prior to the discoveries of Mendel. Thus, by proper breeding, we could eliminate the greatest cause of insanity, heredity.

The three other great causes, alcoholism, syphilis, and traumatism, would still require consideration. Alcoholism would, in all probability, be eliminated with the elimination of the neuropathic taint, since this condition is almost invariably dependent upon a neuropathic make-up. Syphilis has received a mortal wound from salvarsan and its allies. And traumatisms play an entirely unimportant part in hereditary insanity. So that we can assert with certainty that if we systematically apply sterilization, we will confer the blessing of a cleaner neuropathic make-up upon posterity than has been granted our own, or former generations. It would have little effect, for the present at least, upon the vast army of sane neuropaths that contributes so largely to the root, trunk, and branches of our family tree. But it would eliminate a few defective twigs, and might lead to more extensive pruning; and even a little pruning is better than none.

It will be pointed out that incompetent surgeons would be likely to do bungling, ineffective, and dangerous work, if the operation for sterilization were performed by any but specially qualified operators. This is, of course, true. But this offers no insuperable difficulty, as exemplified by the laws governing the commitment and care of the insane at present. In most enlightened communities only specially qualified physicians are allowed to pass

upon insanity officially. And in the near future surgery will only be practiced by men proved competent for the work.

## THE DIFFERENTIAL DIAGNOSIS BETWEEN PNEUMONIA AND APPENDICITIS.*

By GUSTAV F. BOEHME, Jr., B.S., M.D.,

NEW YORK.

ASSISTANT VISITING PHYSICIAN, OUT-PATIENT DEPARTMENT, DEPARTMENT OF MEDICINE, BELLEVUE HOSPITAL; SURGEON TO THE WEST SIDE GERMAN DISPENSARY AND HOSPITAL; CLINICAL ASSISTANT, DEPARTMENT OF NEUROLOGY, VANDERBILT CLINIC.

To the layman, and indeed to some practitioners, this topic will seem somewhat astounding. Yet an error in judgment is frequently made between the two conditions, much to the chagrin of the physician or surgeon making it and to the detriment of the patient.

The differential diagnosis is often not easy. In fact, in some cases it is impossible for some hours to tell with which condition one is dealing. The point of differentiation are few until definite signs of lobar pneumonia develop. The following series of cases will probably demonstrate this fact:

Case I.—L. B.; native of United States; age, 30. Family history, negative. No history of tuberculosis in the family. Previous history, an engraver by occupation. Very regular in his habits: non-alcoholic; smokes tobacco in pipe moderately. No venereal disease. Gives a history of frequent coughs with what is described as "malaria." No blood examination had ever been made. Always perspires profusely.

Present Illness.—Two days before examination had a slight cough. One day later noted that he perspired freely, and coughed somewhat more. Was markedly constipated. Took a five-grain blue mass pill, but with only a slight result. Then began to complain of a severe pain in his iliac region, for which he desired medical attention.

Temperature, 104.8°; pulse, 100; respiration, 28, short and catchy. No expiratory grunt. Alæ nasi dilate somewhat with each expiration. Had never vomited.

Examination of the chest gave negative results save for a slight râle occasionally with expiration over the right base.

The abdomen was distended and there was no abdominal respiratory movement. The right rectus was as tense as a board and pressure as slight as laying the finger on Monroe's or McBurney's points elicited great tenderness. The patient was very tympanitic, and said he felt very constipated. Calomel, one-fourth grain every ten minutes for eight doses was ordered, with a dose of Epsom salts in the morning. An enema was also given at once. No opiate was administered.

Leucocytosis of 22,000; Polynuclears, 78 per cent. The diagnosis hung between pneumonia (central) with diaphragmatic pleurisy and acute appendicitis.

Seen four hours later the temperature had fallen to 101°; pulse, 88; respiration, 28, but still purely costal in type and catchy. Physical signs remain the same. An ice-bag over the appendiceal region was ordered. No opiate administered. The next morning, eight hours after the first visit, at the right base in the postaxillary line a patch of bronchial breathing with bronchial voice was made out. Temperature of 104.6°; pulse, 120; respiration increased to 30. A diagnosis of probable diaphragmatic pleurisy with central pneumonia was made, which by evening was entirely substantiated by the physical signs and symptoms. The right rectus was no longer tense and in one day all tenderness had disappeared.

This case presented all the cardinal symptoms of appendicitis except vomiting: viz., rigidity, tenderness over the cardinal points, constipation, fever, and leucocytosis, with none of the signs of pneumonia excepting a slight increase in the respiration rate.

Case II.—While still a medical student I was shown a case which presented a similar picture excepting that in this case the patient was operated upon. A man with all the cardinal symptoms of appendicitis was shown by the attending surgeon as one of those cases with a sudden and progressive attack with progressive leucocytosis and polynucleosis. He opened the abdomen and found a normal appendix; he then exposed the liver and biliary passages and found an entirely negative picture. The house staff was then asked whether he had been examined for pneumonia or pleurisy. Such examination had been made. Yet that same evening, as he explained later, a true pneumococcal pneumonia of the right lower lobe was present. This error occurred in one of our largest metropolitan hospitals—where every care in diagnosis is routine.

Case III.—While I was assistant house-surgeon a patient was brought in one morning with a history of chronic constipation with recurrent attacks of pain in the appendiceal region. The cardinal symptoms of the disease were present, including leycocytosis (progressive in character) and vomiting. The attending surgeon examined the case and concurred with the house-surgeon's opinion that a progressive, acute and probably suppurative appendicitis was present. He was therefore operated upon and a normal appendix found; the gall-bladder and ducts were explored and as the peritoneum just below the diaphragm seemed somewhat inflamed, especially about the liver, the case was declared one of perihepatitis. Following the operation the pain still continued and the patient's condition did not improve. That night the change of service occurred and the succeeding house-surgeon, Dr. Geo. Mueller, on the next evening told me that a pleurisy was present, which was followed by pneumonia. The patient went on to recovery.

The probable diagnosis in this case was initially a diaphragmatic pleurisy, followed by a central pneumonia. Whether the clouding of the peritoneum was due to pneumococcic involvement of the peritoneum, I do not know.

Case IV.—M. V. Male, six years old. Was sent to the hospital for examination. Seen by a surgical attendant the diagnosis of acute suppurative appendicitis was made and the case admitted for operation. On admission the patient had a temperature of 103°; respiration, 40 per minute; pulse of 120. The face was flushed, the alæ nasi dilated widely with each expiration; there was heard the characteristic expiratory grunt of pneumonia. The child lay with its knees flexed, the thighs flexed on the abdomen. The right rectus was intensely rigid; there was tenderness apparently over McBurney's and Monroe's points. Physical examination of the chest showed a pleural

*Read at a meeting of the Audubon Medical Society, November, 1912.

friction rib on the right side, below, in the mid-axillary line with a slight area of dullness. Numerous subcrepitant râles could be made out over the lower chest posteriorly and anteriorly. The left chest was clear. A diagnosis of lobar pneumonia was made. White blood count, 17,600, with a polynucleosis of 83 per cent. The next day the lower right lobe was consolidated, bronchial breathing with dullness were distinct. The pleural pain had ceased, the rigidity of the rectus had vanished, and there was no tenderness over the appendiceal region.

Case V.—J. P. A woman of thirty-three was admitted to the surgical wards at 11 P. M. with a diagnosis of acute appendicitis complicating pregnancy. Seen 20 minutes after admission she gave the following history. She was seven months pregnant. She had never had any previous gastro-enteric disease or attacks simulating appendicitis. On the afternoon of the day of admission she had been seized, following a brief chill, by a sharp pain in the epigastrium and right hypochondrium. This pain was sharp and lancinating and aggravated by respiration. Toward evening it had become more limited to the right side and extended from the right hypochondrium down to the iliac region. She had been markedly constipated for two days. At about 9:30 P. M. the pain had become colicky in character and marked in both iliac fossæ. Respiration still was painful. She was seen by a very capable physician and keen diagnostician who sent her to the hospital with the above-mentioned diagnosis. On admission physical examination was as follows: She had an intensely drawn expression, indicative of severe pain, her cheeks were flushed, her alæ nasi dilated with each expiration, which was accompanied by a grunt. The inspiration was shallow and halted apparently by pain. Her temperature was 102.6°; respiration, 40; pulse, 120.

The abdomen was rigid, particularly on the right side, the recti standing out like boards, the percussion note generally was tympanitic. Palpation was extremely painful, especially on the right side. No definite mass could be defined (except the uterus and its contents). As to the points of abdominal diagnosis, the pain was so general apparently that no definite localizing point could be made out.

The heart was normal. On the right side posteriorly at a point just internal to the inner margin of the right scapula and between the fifth and sixth ribs an area of bronchial breathing with a few subcrepitant râles about the size of a 50-cent piece could be made out, otherwise the chest was normal.

The vaginal examination showed two fingers' dilatation of the cervix with active labor occurring. Leucocytosis of 18,000 with a polynucleosis of 91 per cent. was present.

At the time I suggested for diagnosis central pneumonia with pleurisy complicating pregnancy. Such, however, was not the opinion of most of those who saw the case. Dr. J. J. Mooney saw the case and while not offering a definite diagnosis, declared that as labor was progressing and as there were physical signs and symptoms enough to warrant my opinion of the case, advised waiting until labor had been consummated before a definite opinion could be expressed.

The next morning at about 9 o'clock the woman was delivered of a seven-months' fetus, which died almost immediately following birth. Seen at 11 A. M., the area in the lungs, previously described, to my ears still showed bronchial breathing more marked than the night before. Still, doubt existed. The pain, however, had diminished considerably, the tenderness over the recti was not so marked.

The next day, however, the diagnosis was perfectly clear; the lower right lobe on the right side was solid, the middle lobe showed beginning congestion. The patient had begun to cough, the sputum was rusty and on examination showed abundant pneumococci. All abdominal rigidity had passed away. There were no points of tenderness. Crisis occurred on the eleventh day and the patient went on to perfect recovery.

Case VI.—H. P. Age, nine; schoolboy. Four days before admission felt sick after eating a pear. He had a headache and pain throughout the abdomen. The mother sent for a physician who ordered castor-oil and the bowels moved the next day, and ever since the onset of his illness. On the evening of the day of onset he vomited, the vomitus being a dark red. The pain finally settled in the right illac fossa. He had been coughing one week before the onset of his present trouble, his sputum being profuse and white in color. On Monday following the onset of his illness he experienced a chill.

On admission he complained only of intense pain in the right iliac fossa. Physical examination summarized showed: Temperature, 103.8°; pulse, 130; respiration, 44. (1) Rigidity of the right rectus; (2) Tenderness over Monroe's and McBurney's points; (3) Rectal examination negative; (4) A general tympanitic note over the ascending and transverse colon; (5) Flexion of thighs on the abdomen. The heart was normal. Both sides of the chest posteriorly showed crepitant and a few moist râles.

On the right side anteriorly in the fourth interspace an area of suspicious bronchovesicular breathing was made out. I hung between the diagnosis of lobar pneumonia (central, coming to the surface) and acute appendicitis. White blood count, 31,200; polynucleosis of 85 per cent. Dr. Frank D. Gray, under whom I had the pleasure to serve at that time, decided in favor of the latter opinion. The child was operated upon immediately and an acute suppurating appendix was found.

This series of cases presents then some actual experiences, and points to the difficulties which present themselves in the differential diagnosis between the two conditions.

Some declare that error is avoidable in these cases; that routine and careful examination of the chest will always do away with chance errors. I will admit that in the majority of cases this is so, yet there are cases in which the differentiation, early in the process is entirely impossible.

Rose and Carless state that "In a well-marked case (of appendicitis) the diagnosis can never be in doubt. The pain, tenderness, fever, vomiting and constipation, abdominal rigidity, and perhaps tumor, constitute a picture which is quite characteristic. The disease, however, often presents symptoms so varied, and manifestations so protean, that one is never surprised to meet it in all sorts of diverse settings, and many mistakes in diagnosis are made, even by the most skilled clinicians."

Johnson in his "Surgical Diagnosis" declares: "I have moreover seen a very competent surgeon make a probable diagnosis of appendicitis in a case of central pneumonia of the right lung with prob-

able diaphragmatic pleurisy. The muscles of the right side of the belly were quite rigid."

Edwards quotes one case of pneumonia which was operated upon for appendicitis and a second which barely missed the surgeon's knife. In his very instructive paper he declares, "That diagnostic errors and unnecessary operations may be unavoidable."

Feer states that "children of 3 to 7 years of age very often refer the pain (of pneumonia) to the epigastric region. These gastric and abdominal pains are decidedly characteristic of croupous pneumonia. Not infrequently these pains simulate appendicitis, to which also the vomiting, the absence of physical signs in the lungs and the appearance of grave clinical manifestations in the midst of perfect health are added in a misleading manner. They have led to operation in these cases of "pneumo-pseudoappendicitis."

It would seem of value therefore to review the diagnostic points of the two processes and to see what aids for differentiation can be employed.

The subject, I believe, can best be approached by classifying the conditions somewhat as follows: (1) Pneumonia simulating appendicitis; (2) appendicitis simulating pneumonia; (3) coexistence of the two processes; (4) so-called postoperative (ether).

*Pneumonias.*—The first is by far the commonest error made, and as faulty diagnosis (as proven by operation) gives a mortality of 20 per cent. of the cases wrongly operated upon, needs most careful study. As a general statement, it may be said that the error of diagnosis in most of these cases is due to the fact that the abdominal symptoms, especially in children, so far outshadow the respiratory ones that careful thoracic examination is neglected. Yet cases do exist in which the diagnosis is impossible for some time.

An analysis of the cardinal symptoms in the two conditions is requisite.

1. *Pain* in pneumonia is often reflected to the region of the appendix, or other abdominal organs, especially with a diaphragmatic pleurisy. The pain is usually sharp and lancinating, in contradistinction to the colicky epigastric pain, later followed by a dull continuous ache in the right iliac fossa, which is present in appendicitis. Yet the two pains may be very similar even in the adult, and in children, who cannot adequately express the finer differentiations, the two cannot be distinguished.

Again some authorities claim that the pain in pneumonia ceases usually in a characteristic manner, and that this can be used as a differential point. This is a dangerous differential, as with rupture of the appendix or gangrene the pain ceases in most instances at the moment when operative interference is absolutely essential.

2. *Nausea and Vomiting.*—This, if progressive, may point to appendicitis or ileus, yet how often, in children, and even in adults do we find initial vomiting in pneumonia!

3. *General abdominal sensitiveness* at first, finally most marked in the region of the appendix. As a general rule it may be stated that the greatest tenderness is over the seat of the appendix, and that generally it is in the right iliac region. But how often in pneumonia is the pain as intense in the same region! To differentiate the tenderness various differences in the two diseases have been noted. Whitacre, for instance, declares that the tenderness in pneumonia is always superficial, as does Henoch. Others claim there is a hyperesthesia of the skin over the appendix in pneumonia. The same authority declares that in periappendicitis the skin over the appendix can no longer be touched. Deep tenderness is said to be diagnostic of appendicitis, yet in both conditions the rectus may be so tense that deep palpation is impossible.

In my own experience, in pneumonia the abdominal tenderness has been more general and more superficially situated than in appendicitis. In the first and fifth cases cited, the abdominal wall was so tender to touch over the right rectus that even the lightest pressure caused intense pain. It may be stated, I believe, that superficial tenderness is more characteristic of pneumonia than of appendicitis. This is probably due to the fact that the lower dorsal nerves which supply both cutaneous and muscular branches to the abdominal wall, are irritated reflexly by the pleurisy and the beginning pneumonia.

4. *Elevation of Temperature.*—This is practically of no value for differential diagnosis. Both diseases may have a sudden, high elevation of temperature, both may begin with a low grade pyrexia. The temperature of pneumonia tends, however, to rise more suddenly and to a higher point than that of appendicitis; in children this is not true.

5. *Leucocytosis.*—Both diseases show early a leucocytosis with a marked increase in the polynuclear elements. Both, if progressive, show a progressive leucocytosis (Gibson's curve). A low leucocytosis in both is an ominous sign of decreased resistance. The blood count therefore helps but little in the diagnosis.

Thus we find that we can have the five classical symptoms of appendicitis as described by Murphy exactly simulated by central pneumonia with diaphragmatic pleurisy. The order of the symptoms may be the same, and again the symptoms in appendicitis by no means follow in the above order. I have seen only vomiting and elevation of temperature as the first signs. Again, one of the five symptoms may be absent in either of the conditions and the picture still be obscure. It therefore becomes necessary to enter into the further discussion of symptoms.

6. *Facies.*—The so-called "peritonitic facies" is often described as characteristic of appendicitis, and that it is not present in pneumonia. This is probably a differential point, but with this facies, as a rule, appendicitis is past the stage of early diagnosis and begins to show peritoneal involvement. The diagnosis should be reasonably clear in these cases. The dilatation with expiration of the alæ nasi in pneumonia is quite characteristic, but may, in rare instances, especially in children, be closely simulated in appendicitis.

7. *Attitude.*—With appendicitis the patient generally flexes his right knee and his thigh upon his abdomen. This is rare in pneumonia, excepting when there is considerable diaphragmatic pleurisy, when the same attitude may be assumed. In two instances of pneumonia the patient has asked to be elevated, saying that this eased his pain. Whether this relaxed the pressure of the abdominal parietes on the diaphragm, or wether this caused tension from below by the weight of the liver on the diaphragm and thus separated the inflamed parietal from the visceral pleura, I cannot say.

8. *Rigidity of the Abdominal Wall.*—This varies considerably in both diseases. The right rectus may be tense and stand out like a board in both

conditions. Again in both, the wall may be lax. Brewer and Johnson state that there is little or no muscular rigidity in acute catarrhal appendicitis. Johnson cites a case of gangrenous appendicitis in which no abdominal rigidity existed. Whitacre declares that in pneumonia the "rigidity is less circumscribed and is very great." This is true in a great many instances, yet in case one, the rigidity was distinctly limited to the right rectus, while the left side of the abdomen was soft, and could readily be explored. Some authors declare that in pneumonia the abdominal wall relaxes for a moment with each inspiration. This view is diametrically opposed by Edwards, and, I believe, justly.

9. *Distention and tympanites* are present frequently and early in both processes. Butler declares that in pneumonia "it may be so excessive in conjunction with abdominal pain, as to suggest peritonitis."

10. *Constipation* is common early in both diseases, and furnishes no aid in differential diagnosis.

11. *Chill* is by far commoner in pneumonia. It is early and very marked. Outside of vague chilly feelings, chill is rare in appendicitis.

12. *Respiration* in both processes may be very similar. Rapid, and costal in type, the respiratory movement is limited in both conditions, one to limit friction in the diaphragmatic pleura, the other to limit pain in the appendix due to change in intra-abdominal pressure during the movements of the diaphragm.

Yet the careful observation of the respirations will point very clearly in a great many instances to the diagnosis. In pneumonia the respiration rate is definitely increased in relation to the pulse; it is catchy (a sign which should be watched for, as it is very characteristic of the pleural involvement), and what in children is especially of aid, the expiration is accompanied by a grunt. This is rare in appendicitis. Winters points to another symptom, of value as a differential, the reversal in pause between expiration and inspiration, which is quite characteristic of pneumonia in children.

13. *Herpes labialis* when present point strongly to pneumonia, yet the stage of development should be noted, for a pre-existing herpes due to some other cause may be the one present. An early herpes is of marked diagnostic value.

14. *Cough* if present would indicate pneumonia, yet in the asthenic type and in children, cough is frequently absent.

It is therefore evident that all the signs of pneumonia, early in the process may simulate those of appendicitis, and that great care is necessary for their differentiation.

When one remembers that the physical signs of a central pneumonia may be absent entirely throughout the course of the disease (Pfaundler and Schlossman, Butler), and looks upon the so-called post-operative pneumonias following appendicitis (declared a mild catarrhal appendix after, but a progressive suppurating one, before operation), would it not seem that these may have been pneumonias unrecognized initially?

*Appendicitis Simulating Pneumonia.*—This error is not commonly made, yet in children may readily occur. One may briefly consider this under two headings: (*a*) With normal lungs; (*b*) with a previously existing pulmonary condition.

With normal lungs there should be no difficulty in the diagnosis under ordinary circumstances, yet J. B. Roberts calls attention to "a possibility of a secondary congestion of the lower part of the right lung in a considerable number of cases of acute appendicitis in its early stages. "This condition," he says, "may be a possible aid in the diagnosis of acute appendicitis, when the symptoms of the latter are not very definite. Appendicitis, and perhaps other intraabdominal inflammations, may cause atelectasis of the right lung, or a true congestion, because of insufficient action of the diaphragm on the right side." This, then, points to another difficulty in the differential diagnosis of the two conditions, making it almost impossible in certain instances, to state whether one is dealing with a beginning pneumonic congestion due to the pneumococcus, or to one due to appendicitis.

And, as a matter of interest in these cases, the blood examination for the pneumococcus will be of little or no value, for this organism may involve either the appendix (the iliocecal region), as well as the lung and occasion a true pneumococcus septicemia (Porter, Mummery and White).

With a previously existing pulmonary condition, the early diagnosis may be entirely confusing. Râles of all kinds may be heard at one, or both bases and who, with the remainder of the physical signs of pneumonia present, can differentiate them from incipient pneumonia?

The bronchiectatic cavity, the atelectatic area, the localized process, may all simulate pneumonia during an acute attack of appendicitis so closely that diagnosis may be impossible. History in these cases is of great importance, and should be elicited with great care.

*Pneumonia Complicated by Appendicitis or the Reverse.*—This rarely occurs but should be thought of in every case. The knowledge that the constipation and the intestinal distention in pneumonia may cause a recurrence in a previously inflamed appendix should lead one carefully to examine the abdomen in all cases of pneumonia.

*Ether Pneumonia.*—The existence of this process is not denied. But we would call attention to cases in which a so-called catarrhal appendix (or a perfectly normal appendix) is removed, to be followed at once by a pneumonia, on the right side, in the right lower lobe. It would seem that in some of these cases the error had been made and never been recognized by the surgeon.

In conclusion, agreeing with Edwards, it is probably better to remove a normal appendix with an existing pneumonia unrecognized, than to allow a pus appendix to remain, to awaken too late to save the patient from a general peritonitis. This does not speak, however, for any lack of care in diagnosis. Every point should be well weighed, and then a decision reached. Perfect frankness in our errors leads to a more perfect understanding, therefore let us carefully consider and weigh them, and thus gain a true insight into the conditions which may baffle us, even with apparently no hope of solution.

**Pancreatic Transplantation in the Spleen.**—J. H. Pratt and F. T. Murphy note that pancreatic tissue implanted in the spleen and separated from its original vascular and nervous connections can live and functionate for months. A small nodule of pancreatic tissue composed of acini without demonstrable islands of Langerhans prevents the development of diabetes. Death occurs in dogs 187 days after the extirpation of the pancreas.—*Journal of Experimental Medicine.*

# A BRIEF COMPARISON BETWEEN HOSPITAL SERVICE IN GERMANY AND THAT IN THE UNITED STATES; WITH A REFERENCE TO THE REQUIREMENTS FOR MEDICAL PRACTICE.*

By H. J. BOLDT, M.D.,

NEW YORK.

It might seem to one not thoroughly acquainted with existing conditions that, save possibly in number of patients, there is practically no difference in the two countries. As a matter of fact, however, there are several noteworthy dissimilarities. To begin with, the appointment of an incompetent attendant to a large German hospital is a thing unheard of, whereas in our country such appointments are by no means rare. I have known of more than one instance where influence has secured the appointment to hospitals here of physicians almost wholly lacking in practical knowledge of the ailments to be treated in the department to which they were assigned; and I am quite sure that such happenings are likely to continue for many years. Certainly, where men are appointed to fill positions as chiefs in departments for which they have evidenced but scant ability, the best interests of the institutions and their patients cannot be served.

I would point out, too, that the best, the only sure way to become competent is to begin at the lowest rung of the ladder and serve patiently as an assistant without evincing undue eagerness for promotion. Real learning, originality, ability, must eventually impress not only the head of the department, but others as well, and the really competent person will be advanced. Whereas, to make one's self conspicuous in the "climbing up" game is sure to create a disagreeable impression, and is the reverse of likely to profit one in the long run.

Then, too, the power of the attending medical man in Germany is unlimited. He may acquire any appliance or any remedy that he sees fit to use in what he considers proper treatment. He is, in a word, the Czar of the situation.

But of greater, or at least of equally great importance, is the matter of assistants in hospitals. With us, few instances excepted, internes are appointed to serve for a definite time, varying from one to two years; and in most of the large hospitals during this period the interne fills, at regular intervals, the various stations. Unfortunately many—perhaps the greater number—fail to conceive their proper relation to the head of the department in which they serve. They are possessed with the customary American spirit, of looking out primarily and principally for themselves and seeking chiefly their own advantage. This is because the true spirit of principal and assistant has not been cultivated.

In Germany the conditions differ materially. It is customary there for young men desirous of acquiring additional knowledge to secure first a position as a volunteer assistant. Then, should the young doctor show himself in every way satisfactory, he may eventually be elevated by appointment to a regular assistant, which is usually his ambition. As a volunteer he assists in the *Poliklinik* (out-door department or dispensary) and in the *Klinik* (hospital) as directed by one of the regular assistants. He may remain a volunteer for two years or more. I was informed that some clinics oblige the applicants to bind themselves for two years. As a regular assistant, the period is almost unlimited. Eight to ten years or longer is not unusual. But should he do exceptionally good and original work and have been promoted in rank and in title because of the excellence of his work and publications, he may get a call from a university to fill a chair, when a vacancy occurs.

During his assistantship a thesis on some original investigation should be written by him, and if acceptable to the board of critics he is then permitted to establish himself as a private instructor (*Privat Dozent*). In this position his income, usually very meager, and varying with the number of his pupils, his teaching ability, and the clinical material he controls, helps or entirely suffices to defray his expenses.

What very forcibly strikes one who, being conversant with the language, talks with the assistants, is the veneration in which the chief of department is held by all of the younger men. The strict discipline and the careful attention to minute details of custom and rule are remarkable. Even though the first assistant has been promoted to a titular professorship, so that he actually serves as a substitute for the chief during his absence, and though he may do fully as good or even better technical work than the chief, still that reverence, that submission to the slightest wish, that high esteem for the chief remain unabated.

As for the chief, should he desire a certain line of work investigated, a careful study made in a certain direction, all that is necessary is to make the suggestion to one of the assistants, either volunteer or regular, and he may rest assured that nothing will be left undone to secure a successful result. The prosecution is thorough and painstaking, including an intelligent consideration of all available literature on the subject. Suppose, for instance, the chief be desirous of knowing the results of a particular line of treatment. The order is given to a member of his staff, and with the better means afforded of tracing persons in Germany, by reason of the existing police control there, that assistant will be enabled to place all the desired facts fairly well at his chief's disposal. There is, indeed, an unquestioning loyalty to the head of the department, such as, so far as I know, exists in few institutions in our country.

Suppose, on the other hand, one of the volunteers, or one of the junior regular assistants, be desirous of writing upon some theme. Invariably he asks permission of the head of the department, and invariably it is given. And frequently, then, he obtains not only suggestions, but actual aid in the effort from one of his superiors.

From a purely scientific viewpoint proper routine laboratory work in our country is an exception. In Germany it is the rule. Let us take a simple case for illustration: A woman with an eroded cervix. A small piece of tissue, and the curetted scrapings are sent to the laboratory and a careful examination is made by one actually competent to make it. Not infrequently an early carcinoma, or a tuberculous condition is thus recognized. No specimen is ever thrown away—a common occurrence in most of our hospitals—all are carefully examined.

*Read at the meeting of the Society of Medical Jurisprudence, March 10, 1913.

Not only one section, but numerous sections are made, so when the report is returned it may be relied upon. But then—and this is important—the specimen is not destroyed, but carefully labeled and stored, so that serial sections may be made at any time. How very important this is we all know.

Nothing in the history, the *status præsens,* or convalescence is lost sight of. Everything is recorded carefully. It would be inadvisable for the young doctor responsible for these records to be superficial in this or in any other work assigned to him, especially if he aspires to a permanent connection with a teaching institution. And if repetitions of neglect occur he need not expect promotion, nor indeed, if he be a volunteer, to remain long in his position.

It may, in connection with this topic, be appropriate to say a few words concerning the requirements for admission to the study of medicine and those for admission to practice. In Germany they are uniform. A young man must have passed the "Oberprimarium" of the gymnasium before being admitted to the university. The average age of passing is eighteen years. Many do it at the age of seventeen years. How much these requirements vary with us, depending on the medical school, I need not state here. But I wish to assert, and very emphatically, too, that to require a young man to have the B.A. or B.Sc. degree is unfair, in that it is seldom acquired—because of the lax methods of study in this country—before the twenty-first, usually the twenty-second or twenty-third year And that is too long to wait. I do not, however, wish to imply by this that I favor a lesser degree of preliminary education. Certainly our average American college graduate is not possessed of more practical equipment than the German gymnasium graduate. Indeed, he is not nearly so well grounded, being frequently woefully lacking, not only in fundamental undergraduate studies, but in the elementary branches as well. I am sure that where a class of one hundred senior college students and one hundred "Oberprima gymnasium" pupils given an exactly similar examination in Greek, Latin, two modern languages, literature, mathematics, and some elementary subjects—for example, geography and history—the examiner paying close attention as well to the grammar, style, punctuation, spelling, etc., the result would be decidedly in favor of the German class, in spite of its pupils being several years the younger.

The primary fault with us is in our elementary schools. Indeed, our whole school system falls short of a sufficiently high standard. Colleges can do much to compel a better system by requiring the examiners to pay heed not merely to the direct answer to the question of the examination paper, but also to the construction of the answers, the grammar, and the spelling. In a great number of instances the preparation of the American college matriculate has been far too superficial. Too much time has been devoted to matters unconnected with his studies; the examinations are frequently not, in my opinion, sufficiently severe to test the fitness for promotion. The greater number of American students believe that about two hours devoted daily to their studies outside of the class room suffices; whereas the German pupils devote about six hours, and some of them apply themselves eight hours a day. Many advocates of strenuous athletics assert that collegiate sport and collegiate social life are of equal or even greater importance than the actual studies. That, of course, is a matter of personal opinion. I believe that one hour devoted daily to properly conducted physical culture—but that should be compulsory—is sufficient. The German students get plenty of physical development during the year of obligatory army service.

The fact that many medical colleges in this country make an arts or science degree a prerequisite of entrance so delays the aspiring young doctor that, by the time he follows his professional term with experience in medicine, surgery, obstetrics, and the specialties in hospitals where these services are separate for internes, and is in a position to earn a living, he has reached his thirtieth or thirty-first year. And this is too old. Somewhere there has been waste of time. A plan, therefore, must be devised by which our young medical man may be enabled to enter the struggle for existence, properly prepared, at the age of from twenty-four to twenty-five years, as do those across the sea.

In Germany the course of study before one is admitted to practice is six years. There are five years in the medical college, but during the last two years true clinical instruction is given. The candidate must make diagnoses before the assembled class, suggest treatment, and, in appropriate cases, carry it out; the professor subjecting him to an examination on all points in connection with the patient. The last year, the sixth, is called the practical year, resembling largely the final term of interneship in a hospital in our country. This practical year is compulsory, and one is not allowed to come up for the State Board examination without having possessed himself of this clinical experience.

I am strongly of the opinion that in the interest of the people of the United States the leaders in the medical profession here should unite to bring about the enactment of uniform laws governing the admission to the study and practice of medicine. That before a young doctor shall be allowed to take the State Board examination he must have had not less than one year of active clinical experience is of the gravest importance. The plan that now prevails in some hospitals of dividing the different services and compelling an interne to devote from one and one half to two years to one service, affords him an inadequate knowledge for the practice of medicine on a broad basis, in that it limits his practical knowledge to the single field of work that he has been engaged in. And should he elect to take positions in the other services as well, so much time is involved that he reaches the age of thirty before he has finished.

It is obvious, too, from what has been written, that an attendant in a hospital should have the ability to teach, and that he should be compelled to take upon himself that duty.

As a final suggestion, let us have fewer medical colleges, place them under government supervision, and limit them to localities wherein there is abundant material to fit the candidate to enter upon the duties of his profession with sufficient clinical experience. And above all, eliminate commercialism from the study and practice of medicine. In Germany post-graduate instruction to those graduated from German universities is given gratuitously.

Since writing the foregoing I have read a book by Prof. Hugo Muensterberg, of Harvard University, entitled "American Traits." This book

devotes a chapter to education and one to scholarship. I urge, most earnestly, all who are interested in this subject to read that book. There is not a word printed there but can be verified.

## THE TREATMENT OF ERYSIPELAS IN INFANTS BY MEANS OF VACCINES.

By E. MATHER SILL, M.D.,

NEW YORK.

ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY, CHILDREN'S DEPARTMENT; LECTURER IN DISEASES OF CHILDREN AT THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

It has been known for some time that the microorganism of erysipelas is a streptococcus. This microorganism was first obtained in pure culture by Fehleisen. More recent exhaustive investigation and experimentation have demonstrated that Fehleisen's erysipelas coccus is identical with the *Streptococcus pyogenes*, and neither can be distinguished from the other.

Suppuration or abscess occurs in erysipelas, usually when the streptococci are present in large numbers in the tissues outside of the lymph channels, or when there is a mixed infection with the staphylococcus.

My first paper on the use of vaccines in the treatment of bacterial infections in children was published in the Medical Record of August 6, 1910. In this paper (among other infections) I reported in detail and gave temperature charts of two cases of erysipelas in infants which were cured by injections of streptococcus vaccine. Since then eight more cases treated by vaccines have been added to my list.

The ages of these infants were 17, 12, 11, 8, 8, 7, 5, ¾, 5 months and one 8 days respectively. All the cases so treated with the exception of one were cured. Seven cases were treated with streptococcus vaccine alone. One case with combined vaccine (streptococci 50,000,000, staphylococci 500,000,000, colon bacilli 200,000,000) and two cases with Schaefer's mixed infection phylacogen.

Case I.—The case that received the combined vaccine was a case of erysipelas of the abdomen in a poorly nourished Italian child 17 months of age; the temperature was 104.8° F., two, 1 c.c. bottles containing each streptococci 50,000,000, staphylococci 500,000,000, colon bacilli 200,000,000 were given. The child was not seen again for four days when the temperature had dropped to 99.8° F. and the area of erysipelas had considerably diminished, but unfortunately, through some fault of technique possibly, abscesses developed and had to be opened and drained, and the child ran a low temperature and received repeated injections of the combined vaccine for a period of nearly a month, before cured.

Case II.—A child 1 year of age, erysipelas of the leg extending half way up the thigh, temperature 104.6° for first four days, wet bichloride dressing, 400,000,000 mixed staphylococci were given twice. The erysipelas continued to spread over the buttocks, temperature 103.8° F., on the fourth day 80,000,000 streptococci, on the fifth or next day the temperature had dropped to 102.2° F. and although the inflammation had spread slightly higher the whole area of inflammation looked much paler, 80,000,000 streptococci were given and the child was not seen for two days, when his temperature was 101.6° F. and the erysipelas had faded from the leg and thigh. Three days later the temperature was 99.2° F. and the erysipelas had nearly entirely disappeared, 40,000,000 streptococci were given, the next day there was no more signs of erysipelas and temperature was normal.

Case III.—The second case that received the streptococcus vaccine was a child 8 months of age. The infection began at the vulva and the rash had been spreading for a week, having been treated by another physician before it came under my care. When seen the temperature was 103° F., pulse 135, there was marked prostration and pallor. A wet dressing was applied and 80,000,000 streptococci were given on September 18; the next day the temperature was 103.8° F. and the erysipelas had spread about an inch higher; there was marked prostration with pallor. A wet dressing was applied, brandy and 120,000,000 streptococci given. September 20 temperature 103.8°, pulse 125, respiration 44, erysipelas advanced ¾ of an inch up the back and down the leg 1 inch, fading on the abdomen, 120,000,000 streptococci were given. September 21, temperature 103.7° F., pulse 92, respiration 48, pulse weak and irregular. Brandy and strychnine ordered, continuous cold pack, erysipelas had spread scarcely any, and old area fading rapidly, 120,000,000 streptococci were given. September 22, temperature 102° F., pulse 150, respiration 44, quality of pulse good. Erysipelas not spreading, rash had entirely faded, desquamating some, child is brighter and has a good color. Two c.c. of combined vaccine were given, each c.c. contained 50,000,000 streptococci, 500,000,000 staphylococci, 200,000,000 colon bacilli. September 23, erysipelas entirely well, child has diarrhea, temperature 101.9° F., pulse 120.

Case IV.—This was a child 7 months of age with erysipelas of the face and nasal diphtheria. The temperature was 102.2° F., pulse 126; ten thousand units of antitoxin and two c.c. of combined vaccine were given. The following day the temperature was 104° F., pulse 138, respiration 28, and irregular. Five thousand units antitoxin were given and one c.c. of combined vaccine. Next day the temperature was 103° F., the glands of the neck were swollen, but otherwise the child seemed much better; 40,000,000 streptococci were given and the child made an uneventful recovery.

Case V.—This was a child 8 days old with erysipelas of the abdomen and vulva resulting from an infection of the cord of the umbilicus; the temperature was 102.8° F., 40,000,000 streptococci were given, and on the following day the temperature was 101.5° F., and the erysipelas had spread down the thigh to within one-half inch of the knee; 80,000,000 streptococci were given. Next day the child was much better, the erysipelas was fading rapidly, had not spread, and the temperature was normal, 80,000,000 streptococci were given.

Case VI.—Child 11 months of age, with erysipelas of the arm. Infection following vaccination. Temperature was 102.8° F., 40,000,000 streptococci were given. The following day the temperature was normal and the erysipelas was almost entirely well.

Case VII.—This was a child 8 months of age with erysipelas of the leg following a streptococcus infection. On November 14 the temperature was 103° F., with the erysipelas involving most of one leg, 50,000,000 of streptococci were given. November 15, the temperature was 102.4° F. and the inflammation had not spread. November 17, the tem-

perature was 99.2° F. and the redness and swelling had almost entirely disappeared. November 18, the inflammation and redness had entirely gone and the temperature was normal.

Case VIII.—Child 5 months old with erysipelas of the face. September 12, temperature 105.4° F., wet dressing applied. September 13, temperature 101.8° F., 4 c.c. Schaefer's mixed infection phylacogen given. September 14, area of erysipelas diminishing and fading, temperature 102° F., 5 c.c. Schaefer's mixed infection vaccine given. September 16, temperature 99.8° F., erysipelas almost entirely gone. September 17, temperature normal, face cured.

Case IX.—This was a malnourished, underweight child, three weeks of age. It had a large umbilical hernia, thrush, and a vaginitis. The erysipelas involved one leg and the temperature was 104.6° F. Streptococcus vaccine, 80,000,000 bacteria, was given and a wet dressing applied. The case did not report again at the clinic, but the mother reported that three days after the injection the child had a convulsion and died.

Case X.—This was a child one year of age with erysipelas of the arm. On June 26 the temperature was 105° F., and pulse 162, one c.c. of Schaefer's mixed infection phylacogen was given. On the 27th the erysipelas was still spreading down the upper part of the arm toward the hand, the temperature was 103.6° F. and the pulse 146, three c.c. of mixed infection phylacogen was given. On the following day the inflammation had reached the hand but was fading above, the temperature was 100° F. and pulse 150, two c.c. of phylacogen was given. June 29, temperature 99.8°, pulse 164, two c.c. of vaccine was given. June 30, temperature 100° F., pulse 150. Two c.c. of mixed infection phylacogen given. July 1, temperature 98° F., pulse 136. Child entirely well.

Dock states that erysipelas in the first month of life is almost always fatal, but after that time the danger decreases directly with the age. Kerley says that erysipelas is a particularly fatal disease in infants, 95 per cent. of the cases being fatal in the new born, and 50 per cent. of his cases occurring under one year being fatal. In view of the fact that only one of my cases treated with the streptococcus vaccine was fatal (or a mortality of 10 per cent.), although some of the cases were in very young babies and others were rachitic or badly nourished infants, with poor resistance to overcome such an infection, I cannot but believe that the use of the streptococcus vaccine in infantile erysipelas is by far the most efficacious treatment at our command and I believe it should be used in large doses at twenty-four hour intervals together with the use of local measures.

104 West Seventy-sixth Street.

---

**Edema of Conjunctiva from Acute Frontal Sinusitis.**—A. J. M. Wright reports the case of a man who was first seen on May 23 with severe left frontal headache, and edema of the inner portion of the left conjunctiva, lids and orbit, and with a conjunctival hemorrhage. There was a history of a similar attack fifteen years ago. There was pain on extreme deviation of the eyes to the left, with slight diplopia. The septum was deviated to the left, blocking that side. No nasal discharge. The septum was resected on May 26, with relief of the headache, and the swelling subsided. There has been a little left nasal discharge since the septal operation.—*Proceedings of the Royal Society of Medicine.*

## Medicolegal Notes.

**Malpractice — Nonexpert Evidence.** — Action was brought against a physician and surgeon for malpractice in the treatment of the plaintiff's finger. The defendant was attending another patient at the time of the injury, and did not reach the plaintiff until about two hours after it occurred, when the hand was considerably swollen. After an examination he decided that there was a partial dislocation and also a slight fracture of the bone, and he undertook to reduce the dislocation, treating it in the usual way by placing splints and bandages on the finger. He visited her two or three times, each time examining and treating the finger, when she complained that it caused her great pain. Subsequently she returned to her work as saleswoman in a store, but complained that she suffered much pain from the injury. She called at the doctor's office a number of times, and was given treatment, but frequently expressed dissatisfaction that greater progress towards recovery was not made. In about five weeks she discontinued her visits to the defendant, and consulted several others, one of whom, about eighteen months after the injury, amputated the finger.

In her petition, the plaintiff charged, not that the defendant lacked professional skill or learning, but that he carelessly and negligently failed to reduce the dislocation, and failed to discover the condition of the finger, or to skilfully and properly treat it afterwards.

A witness was permitted by the trial court to testify that the plaintiff suffered intense pain all the time. This testimony was held inadmissible as being not in regard to the manifestations of suffering, but a mere naked conclusion that the pain was intense. Another nonexpert witness was allowed to say that the patient's hand was a very sick member; that it was in bad condition; that the joint looked to be out of place. This also was inadmissible. Nonexpert witnesses may testify as to external appearances and manifest conditions observable by any one; but whether a surgical operation has been performed with a reasonable degree of skill, learning and care, such as is ordinarily possessed and exercised by surgeons and physicians in the treatment of their patients, is a question of science, and is to be established by the testimony of surgeons and physicians having special skill and knowledge, and not by unskilled witnesses, who are without training or knowledge as to the injuries sustained, or the art of treating them. Statements made by the plaintiff to witnesses weeks after the injury that she suffered great pain were also excluded as hearsay, being declarations of a self-serving nature.

It was held that nothing in the evidence warranted an instruction to the jury on the theory that the defendant had held himself out as a specialist, or that the degree of skill and care required of him should be higher and greater than is required of the ordinary physician and surgeon.

Judgment for the plaintiff was reversed and a new trial ordered.—Johnson v. Powell, Kansas Supreme Court, 123 Pac. 881.

**Examination as to Witness's Professional Fees.**—In an action for personal injuries a physician testifying for the plaintiff, whom he had attended, testified that he did not attend the plaintiff on a percentage of any recovery he might get for the injury, but that the patient was to pay him as any other patient would when he obtained the money to do so. It was proposed to ask him on cross-examination if he was charging the plaintiff the same as he did another specified person, apparently with the object of then developing the fact that he had charged such third person a percentage. The trial court refused to allow the question, and it was held, on appeal, that such refusal was within its discretion.—St. Louis & S. F. R. Co. v. Clifford (Texas), 148, S. W. 1163.

**Insurance—Misrepresentations as to Health.**—An applicant for insurance stated that he had never had calculus or gravel; that he had never had any other sickness, disease or injury; that he had not consulted a physician within the preceding five years; that he was never under the care of a physician; and that he had no ailment, disease, nor suspicion of any. All of these statements were untrue, and known to be so by the insured's wife and the insurance company's soliciting agent, who knew that the insured was not in good health, and that he had suffered a surgical operation. In an action on the policy it was held that the insurance company was not bound by the agent's knowledge, nor estopped to rely on breach of the warranty as complete defense.—Wilhelm v. Order of Columbian Knights, Wisconsin Supreme Court, 136 N. W. 160.

## ANALYSIS OF THE GASTRIC SECRETION.

WITH the introduction of test meals in the study of the gastric secretion it seemed as if accurate understanding of the various disturbances of gastric function had been arrived at, and indeed a great deal has been added to our knowledge of this function by such means. Recently, however, it has become understood that the test meal removed by the stomach tube represents the results of the several elements in gastric digestion, and the examination of its chemical and physical properties cannot throw light upon the disturbance of anyone of the elements. The normal secretory activity of the stomach is now subdivided into three phases, thanks to the studies of Pavlov and his coworkers: First, reflex secretion, occasioned by sight of food and its mastication; this secretion is, of course, of nervous origin and depends upon the activity of the vagus nerve. The second phase is the so-called chemical phase, and has been elucidated by the discovery by Edkins (1906) of a "gastric secretin" in the submucous layer of the pyloric part of the stomach. As soon as food enters the stomach this "gastric secretin" combines with some of its elements or with products of their digestion, is then absorbed into the blood, and thus reaches the fundus of the stomach, where it occasions secretory activity of the glands of the fundus resulting in the secretion of acid gastric juice. Workers in Pavlov's laboratory (Drs. Gross and Krjishkovsky) have shown that the fundus of the stomach secretes no juice whatever, when isolated from the rest of the stomach; there is, therefore, no reflex chemical secretion in this portion of the stomach, all of the secretion being occasioned by the hormone action of the "gastric secretin." The third phase of gastric secretion is due to the entrance of food from the stomach into the small intestines and the reflex effect of the intestinal secretion upon gastric activity. This phase has not yet been thoroughly studied.

These considerations have led A. Z. Bilin to attempt to separate at least one phase of gastric secretion in the study of gastric juice by means of test meals, namely, the reflex phase, chiefly due to the presence of the food in the mouth (*Russkii Vratch*, Vol. XII, No. 3, 1913). In order to effect this he has modified the usual Boas-Ewald test breakfast by drying and powdering the two pieces of bread or the roll usually given, mixing it with the requisite amount of tea and then administering the mixture through the stomach tube. The resulting secretion could thus represent the purely chemical phase of gastric secretion and not the reflex phase. In repeating the test meal in the usual manner, he was enabled to tell the "reflex" fraction in the total secretion obtained.

Very uniform results were obtained with persons having supposedly a normal digestion, the chemical fraction of the gastric juice being on the average 64 per cent. and the reflex portion 36 per cent. of the total secretory work of the stomach. Of course, these figures are correct only for the conditions present, namely, for the gastric juice excited by the administration of a Boas-Ewald test meal.

In examining several cases of hypochylia Bilin found that in some of them the deficiency in secretion was due to the deficiency of both elements, the chemical and the reflex; in one case there was almost complete absence of the chemical element in secretion, which pointed, of course, to some deficiency in the "gastric secretin" mechanism of gastric digestion; in two other cases there seemed to be complete failure of the reflex mechanism and therefore the reflex element of secretion. Following these findings, Bilin thinks that it is justifiable to divide hypochylia into three different forms, namely, mixed, humoral, and nervous gastric hypochylia. He undertook similar studies in cases of hypersecretion, and here, too, found that now one, now another element of the secretory mechanism was at fault.

Bilin points out in conclusion the practical significance of the results obtained by his method, for they explain both the successes and the failures of the usual therapy; for instance, the use of oil as food, and of atropine is sometimes quite without effect upon hypersecretion because these substances act upon the chemical phase of secretion only and cannot be effective when the hypersecretion is due to increased reflex irritability. It is possible that more rational treatment for each individual case may be derived by following the author's method of analyzing the elements of gastric secretion.

## DECREASING THE RISK OF TONSILLECTOMY IN SEPTIC TONSIL.

THE profession represents jointly three conceptions in regard to the necessity for tonsillectomy. One is routine extirpation another extirpation on strict indication only, while the third involves doing away with the operation altogether. That deprivation of the tonsils causes symptoms *per se* has never been proven, and with our rapid advances in the knowledge of internal secretions we find no note of this sort in respect to these bodies. Extirpation of lymphoid structures can at most result in some compensatory hypertrophy elsewhere. Naturally, however, the organ must subserve some physiological purpose, perhaps, as often claimed, a part of the animal defense against microorganisms. This very familiarity with bacterial life, on the other hand, makes the tonsil oftentimes instead of a barrier a dangerous port of entry for germs.

At a recent meeting of the Berlin Laryngological Society (*Berliner klinische Wochenschrift,* February 17) Halle read a paper on decreasing the risk in tonsillectomy, which caused an extensive discussion. He opposes strongly routinism, and when removal seems strictly indicated varies the method with the case. He prefers West's operation for adults and Sluder's for children. Great care must be taken not to injure the soft palate. The most momentous dangers are operative and postoperative hemorrhage. In such cases we should never temporize, but grasp the bleeding point with artery forceps and use torsion. Ligation is never necessary. Hemorrhage occurs chiefly at one of three points, viz., the upper pole, in the middle of the wound, and on the porterior wall of the arcus palatoglossus, and the bleeding points should be sought here.

Senator, in discussing this paper, alluded to the lack of material which had been followed up for many years. Extirpation of septic tonsils is a comparatively new operation. Hölscher found that internists are in many cases advocates of tonsillectomy for their patients. Levy stated that recurrent peritonsillitis or quinzy was not an indication for complete tonsillectomy. Sobernheim dwelt on the newly established relationship between tonsillitis and nephritis. He would make chronic nephritis an indication for tonsillectomy if the tonsil was in a state of chronic infection. An exacerbation of the tonsil might lead to one in the kidney.

Wagener claimed that quinzy is not followed by rheumatoid infection, but as soon as the tonsil is removed we get no more peritonsillitis. West spoke of the digital method of enucleation, an old procedure recently revived by Matthews in the United States. Claus related a case in which the operator thereby infected his finger. Meyer stated that the finger method, which is intended to minimize the hemorrhage, is to be found in Celsus. West believes that bloody extirpation is more conservative in the end than any blunt procedure. He divides the posterior arch behind the tonsil, thus doing the most critical step first. He then detaches the lower pole and prolongs the incision upward to free the tonsil. The advantage claimed is that the clean incisions favor rapid and clean healing and prevent complications due to infection.

## SOME NEW ASPECTS OF PITUITARY DISEASE.

The progress that has been made during the past two years in the experimental anatomy, physiology, and pathology of the pituitary gland has stimulated clinical observations in this field to such an extent that the various symptoms and symptom complexes set forth by Cushing and his coworkers are recognized with increasing frequency and accuracy, new and interesting observations being thus added to the previous experimental work. In a recent number of the *American Journal of the Medical Sciences,* Cushing presents a short summary, embodying the more recent views as to the classification of the various clinical syndromes typical of hypophyseal disease, and instances a few cases characterized by mixed syndromes. These cases demonstrate quite clearly how disturbances of the anterior and posterior lobe functions (either hypo or hyper) may be associated in the same individual.

The posterior lobe, as has been shown, is probably the portion of the gland which gives rise to an external secretion which is discharged through the infundibular stalk into the cerebrospinal fluid. The anterior lobe, on the other hand, is the internal secretory portion of the gland and discharges its secretion into "the large sinusoidal blood channels which traverse it."

Among the causes of posterior lobe hypo-function are: experimental ablation of the lobe, obstruction of the infundibular stalk, tumors or any other pathological lesion which interferes with the discharge of its secretion. On the other hand hyperfunction of the pars posterior is attributed to functional disturbances and feeding with gland extracts.

Disease of the pars anterior seems also to be capable of causing hypo- and hyper-function, Frölich's syndrome being a type of the former while acromegaly is a type of the latter. In both of these syndromes there may be associated changes in function of the posterior lobe, heightened activity being often found with acromegaly and lowered activity with Frölich's type (dystrophia adiposogenitalis). Still other groups of cases show a hyposecretion of one lobe in combination with a hypersecretion of the other. Other instances are given, fewer in number, when a primary hypofunction of one lobe (whether due to immediate or distant cause) may be followed by hyperactivity of the other lobe and vice versa.

Clinically the type of symptoms in the various disturbances of each lobe of the gland may be summarized as follows: (1) Hyperactivity of the anterior lobe gives rise to skeletal overgrowth—possibly to hypertrichosis and certain cutaneous manifestations—in brief, acromegaly. (2) Hypoactivity of the anterior lobe is evidenced by preadolescent failure of development in the osseous system and secondary sexual characteristics, etc. (3) Hyperactivity of the posterior lobe causes lowered nutrition and a decrease in carbohydrate tolerance, moist skin, etc. (4) Hypoactivity of the posterior lobe leads to adiposity—higher carbohydrate tolerance, subnormal temperature, somnolence, dry skin, polyuria, polydipsia—in short, the opposite symptoms to the above.

Every clinician is probably familiar with one or another of these syndromes, but their association with one or another group of pituitary symptoms, either as a whole or in part, has not received sufficient attention and it is for that reason that Cushing's recent work is of interest particularly to clinicians.

Treatment of individual or combined syndromes, as evidenced by pituitary disease, has so far been limited to administration of extracts of the gland and surgical interference. Both of these methods are in their infancy and have met with success only in a limited and selected number of cases. The report of a larger number of cases and increased research are eagerly awaited.

### Prognosis of Chronic Nephritis.

The extreme variation in the duration of this affection—given by authors as "from six months to two or three decades"—makes the question of prognosis one of abounding interest. Tests for renal insufficiency are more or less untrustworthy. Of late years, however, these have been checked up by improvements in the technique of blood examinations for retained nitrogen. Folin's method makes it possible to make blood tests with but 5 to 10 c.c. of blood serum, whereas formerly tenfold this quantity was required. At a recent meeting of the Berlin Urological Society (*Berliner klinische Wochenschrift*, February 24), Strauss discusses the subject of residual nitrogen in the blood. In normal subjects this amounts to about 50 mgm., while in uremia it may rise to 250 mgm. When 150 mgms. are reached the prognosis becomes grave. On the other hand a figure between 50 and 75 has no significance. The figures at which a prognosis may not be hopeless are those between 75 and 150, the risk increasing with the amount. Discussion of this paper brought out the general belief that the best urinary tests to use for corroboratory purposes are the potassic iodide and sodium chloride methods.

## News of the Week.

**Medical Expert Testimony.**—The committee on medical expert testimony of the New York State Medical Society has caused to be introduced into both houses of the State Legislature a bill to amend the present judiciary law in relation to examining physicians, by adding the following paragraph: "Sec. 31. Examining Physicians.—In a criminal action or proceeding or in a special proceeding instituted by the State writ of habeas corpus or certiorari to inquire into the cause of detention, in which the soundness of mind of a person is in issue, the court in which, or the judge or justice before whom, the action or special proceeding is pending may appoint not more than three disinterested competent physicians to examine such person as to his soundness of mind at the time of the examination. Any examining physician may be sworn as a witness at the instance of any party to the action or proceeding. The compensation of such examining physician for making such examination and testifying when certified by the presiding judge or justice of the court or judge or justice making the appointment, shall be paid out of any funds available for the payment of and in the same manner as other court expenses." This bill has been carefully drawn by an expert on constitutional law, who has taken into consideration the laws of all the other States, and it is his belief that it will stand the constitutional test. The committee of the State society, believing that the abuses of medical expert testimony have been and are shameful, hope that the medical profession of New York will endorse the bill and give it hearty support.

**Harvey Society Lecture.**—Prof. John Howland of Johns Hopkins University will lecture before the Harvey Society on Saturday evening, March 29, at 8.30 o'clock, at the New York Academy of Medicine on "The Scientific Basis for the Artificial Feeding of Infants."

**Mount Sinai Hospital.**—Through the generosity of Mr. Samuel Sachs and Mr. Harry Sachs of New York, Mount Sinai Hospital has received a gift of $125,000 for the support of free beds in the neurological department, in memory of Joseph and Sophie Sachs. The hospital has opened a new ward for children suffering from nervous diseases, and the men's and women's wards of the neurological division have been enlarged. One of the new buildings which the hospital is about to erect will be designed with especial reference to the requirements of a thoroughly equipped neurological institute.

**Convalescent Home.**—The directors of the Winifred Masterson Burke Relief Foundation announce that contracts aggregating more than $1,000,000 have been signed for the erection of the Home for Convalescents at White Plains, N. Y. Construction is to begin at once, and it is expected that the buildings will be completed in less than two years. The home will occupy a site comprising 60 acres of land, and the present plans call for the erection of eight buildings, which will accommodate 300 persons. Additional buildings will be erected as required.

**Lectures on Dermatology.**—The Governors of the New York Skin and Cancer Hospital announce a course of clinical lectures and demonstrations on the surgical diseases of the skin to be given by Dr. Bulkley in the Out-Patient Hall of the hospital on Wednesday afternoon from April 2 to May 7, at 4.15 o'clock, and to be followed by a lecture on the surgical treatment of malignant disease on May 14 by Dr. Bainbridge at the same place and time. Each lecture will be illustrated by cases, models, colored plates, photographs, etc., and the course will be free to members of the medical profession on presentation of their professional cards.

**Association of Orificial Surgeons.**—The spring clinic of the American Association of Orificial Surgeons will be held in the surgical amphitheater of the Hering Medical College, Chicago, from April 23 to 26, inclusive. Dr. E. H. Pratt and his assistants will operate on clinical patients, demonstrating the fundamental principles of orificial surgery as applied to the treatment of chronic diseases and an adjunct to major surgery in general.

**Department of Social Welfare.**—The New York Association for Improving the Condition of the Poor has received from Mrs. Elizabeth Milbank Anderson of New York a gift of $650,000 which makes possible the establishment by the association of a department of social welfare, to conduct investigations for the purpose of demonstrating the practicability of preventive and constructive measures. All of the munificent gift will be used for this sort of research work, none being applied to the relief of individual cases. A tentative program of some of the practical work to be undertaken includes a committee on public health and hygiene, which will control the public baths maintained by the association, cooperate with the city officials in endeavoring to popularize public bathing facilities and to make the floating baths sanitary, and conduct an educational campaign for the extermination of common disease carriers, such as the house fly and the roach. The committee on welfare of school children will make a scientific inquiry into the subject of ventilation of school buildings, support the work of serving hot lunches at cost in certain schools, and examine into the present system of medical inspection of school children, methods of cleaning school rooms, etc. The director of the new department has not yet been selected.

**City Death Rate.**—During the week ending March 15 the death rate in New York City was again slightly increased. The total number of deaths was 1,848 and the rate 17.94 per thousand of population, as compared with 1,602 and a rate of 16.15 for the same week of 1912. For the first 11 weeks of the year the death rate was 15.79 as against 15.68 for the corresponding period of last year.

**Personals.**—Dr. F. F. Wesbrook, Dean of the Medical Department of the University of Minnesota, has been appointed president of the University of British Columbia at Vancouver, and it is expected that he will take up his new duties during the coming spring.

Dr. E. U. Lewis of East Dubuque, Ill., was on March 10 elected mayor of the town.

Dr. Robert Wilson, Jr., was on March 15 re-elected Dean of the Medical College of the State of South Carolina, which recently became a State institution.

Dr. Harry H. Archer, surgeon in the New York Fire Department, on March 20 was presented the department medal for long and valorous service as medical officer. This is the first time in the history of the department that the medal has been given to a civilian.

**Investigate Spotted Fever.**—The United States Public Health Service has ordered Surgeon L. D. Fricks to Bitter Root Valley where he will study conditions and attempt to eradicate the spotted fevre tic.

**Walking Smallpox.**—According to Health Commissioner Lankester of St. Paul, Minn., "walking smallpox" is prevalent throughout the Northwest.

**Report on Friedmann Cure.**—The only authoritative report on the Friedmann tuberculosis cure so-called, which has been given to the public sounds rather tame after the vivid newspaper stories of "apparent cures" and "marked improvement one week after injection." Surgeon Blue of the Public Health Service issued the following statement in Public Health Reports of March 21: "On March 8 the Secretary of the Treasury on the recommendation of the Surgeon General of the Public Health Service, caused a board of medical officers to be detailed to make a thorough investigation of Dr. Friedmann's alleged cure for tuberculosis. These officers proceeded immediately to New York and arranged with Dr. Friedmann for demonstrations of his remedy upon persons suffering from tuberculosis. These demonstrations are being carried on in certain New York hospitals through the courtesy of their respective authorities, and will be continued until sufficient information has been obtained for the forming of an opinion as to the merits of the treatment. Dr. Friedmann has submitted to the board a culture of the bacteria which he states are used in his method of treatment. In addition to the observation of persons under treatment by Dr. Friedmann, the board of officers will make experiments to ascertain whether this culture is as Dr. Friedmann claims, harmless to warm-blooded animals. Considerable time will necessarily be required to carry out these investigations. The work will be carried out as rapidly as possible. In the meantime the public is informed of the inadvisability, in the great majority of cases, of traveling long distances in the hope of receiving the treatment, as those selected for demonstration purposes constitute only a small proportion of applicants. Certain statements purporting to be expressions of the board of officers of the Public Health Service carrying on the investigation have appeared in newspapers. These officers have expressed no opinion and will not be in a position to do so until the work has advanced sufficiently far to warrant some conclusion in regard to Dr. Friedmann's treatment." It is reported that Dr. Friedmann will shortly return to Germany.

**Sydenham Hospital.**—A gift of $100,000 from Mr. Isaac Guggenheim has been received by the directors of the Sydenham Hospital, New York, to be added to the building fund of the institution. Plans have been made for the erection of a six-story building to contain 200 beds, double the capacity of the present hospital, and for this the sum of $350,000 is required. The directors hope to raise this amount within the present year.

**Flower Hospital to Build.**—Plans have been filed for the erection of a new building for the Flower Hospital, New York, to be used exclusively for private patients. It will be situated on the southeast corner of Avenue A and Sixty-fourth street and will cost about $140,000. The building will have a façade of brick and limestone in the Georgian style, and will be equipped with every possible hospital appliance.

**Disease Decimating Indians.**—The Public Health Service in a recent report gives the results of an investigation of disease among the Indians which was authorized by Congress in 1909. Nearly 40,000 Indians on all the reservations were examined by the surgeons, who state that tuberculosis is prevalent and that 22 per cent. are victims of trachoma, hundreds being totally blind. They recommend education in personal hygiene, the construction of better houses, a visiting nurse system, and segregation of those suffering from trachoma.

**Gifts to Charities.**—By the will of the late Mr. C. H. De Silver of Brooklyn, N. Y., the Brooklyn Eye and Ear Hospital, the House of St. Giles the Cripple, Garden City, and the Home for Destitute Children, Brooklyn, receive bequests of $2,500 each.

**A Rash Assertion.**—Dr. Friedmann was shown yesterday a copy of the MEDICAL RECORD, in which Dr. Karl von Ruck of Asheville, N. C., raised the doubt that Dr. Friedmann's tubercle bacilli derived from the turtle might not always remain nontoxic, or avirulent. This is what Dr. Friedmann said in reply: "My culture contains live bacilli which are nonvirulent and which will remain nonvirulent. Once nonvirulent, always nonvirulent. There is nothing to make them virulent. You can't make an apple out of a pear, can you?"—*Sun.*

**The Late Dr. Kingman B. Page.**—At a recent meeting of the Medical Board of the People's Hospital, New York, the following resolutions were adopted: *Whereas,* Death has suddenly ceased the activities and affiliations in life of our late colleague, Kingman B. Page, M.D., be it *Resolved,* That in his untimely decease the Medical Board and Board of Directors and Allied Organizations of the People's Hospital in the City of New York have sustained a lasting personal and professional loss, and be it *Resolved,* That in his demise we feel the absence of one whose professional enthusiasm was a real inspiration, whose loyalty to the People's Hospital was a treasured example, whose devotion to the science and art of medicine was an elevating impulse and whose self-sacrifice in the service of

fellowman was a humanitarian principle, and be it *Resolved,* That a copy of these resolutions be spread upon the permanent records of the Medical Board of the People's Hospital in the City of New York, and that an engrossed rescript of them be forwarded to the bereaved family in token of sympathy and fellowship in sorrow and affliction.—Victor Cox Pedersen, Chairman of the Committee on Resolutions.

**The Late Dr. Archibald E. Isaacs.**—A special meeting of the Medical Board of the Beth Israel Hospital, called for the purpose of taking action on the death of Dr. Archibald E. Isaacs, was held at the hospital on March 14, 1913. The following resolutions were unanimously adopted: *Whereas,* Death has claimed and taken from us Dr. Archibald E. Isaacs, who, in the many years of our mutual contact has become endeared to us by reason of his sterling qualities as a man, his earnestness as a colleague, his devotion to his profession and his contributions to its progress, and *Whereas,* Dr. Archibald E. Isaacs has been taken from us at the height of a successful professional career, made so by his own energy and ability, just as he was about to realize the fruits of the self-sacrificing labor and efforts he gave to the cause of humanity, therefore be it *Resolved,* That we give expression to the feelings of heartfelt sorrow that overwhelm us on the occasion of his untimely death; we feel that by his departure in the prime of life and in his uncompleted career, the cause of humanity has lost an ardent advocate, medicine a brilliant devotee, and the Beth Israel Hospital an earnest and able worker, and be it further *Resolved,* That we extend our most sincere condolence to his sorrowing family in this, their sad affliction; their grief is great in the loss of a loving son and husband, and devoted father; may he live in their memory for his love and goodness, and in our memory for his deeds and accomplishments, and be it further *Resolved,* That a copy of these resolutions be spread on the minutes of this board, a copy be sent to the bereaved family, and copies be forwarded to the press for publication.—L. J. Ladinski, M.D., Acting Secretary; J. E. Reinthaler, M.D., President, Medical Board.

The Eastern Medical Society of New York at a recent meeting also adopted the following resolutions: *Whereas,* We have learned with deep sorrow of the death of our beloved member and former president, Dr. Archibald E. Isaacs, whose kind disposition and sterling qualities, and whose ability, earnestness, and devotion to duty have gained for him the regard, esteem, and affection of the members of the Eastern Medical Society, and *Whereas,* Dr. Archibald E. Isaacs was one of the founders and former president of the society, and as one of its active members, he has at all times given freely of his counsel, time, and efforts to promote the interests and welfare of the Eastern Medical Society, and *Whereas,* His professional ability and skill and his self-sacrificing service in behalf of the poor have earned for him a position of honor and distinction in the medical profession and have gained for him the love and esteem of the laity. Be it *Resolved,* That the society record the sentiment of its members that by the untimely death of Dr. Archibald E. Isaacs, a worthy, distinguished, and inspiring career has been cut short, the cause of humanity has lost an ardent champion, the medical profession an exemplary member, and the Eastern Medical Society an enthusiastic and earnest worker, and be it *Resolved,* That the society extend its sincere condolence to the sorrowing family in their loss of a loving son and husband and devoted father. And be it further *Resolved,* That a copy of these resolutions be spread on the minutes of the society and that a copy be sent to the bereaved family and the medical press.—Dr. L. J. Ladinski, Chairman of the Committee.

**Obituary Notes.**—Dr. Ira Van Gieson of this city died March 24 from interstitial nephritis, after an illness of several weeks at the age of 47 years. He was born in New York and received his medical degree from the College of Physicians and Surgeons in 1885. He was for a time instructor at the College and later was director of the Pathological Institute. He was well known as a pathologist and at the time of his death was connected with the research laboratory of the Board of Health. He was the son of Dr. Ransford E. Van Gieson of Brooklyn, who survives him.

Dr. P. B. Stewart of Chetek, Wis., a graduate of the University of Vermont, College of Medicine, Burlington, in 1898, died after a short illness on March 1, aged 45 years.

Dr. James Edward Blair of Burlington, N. J., a graduate of the University of Pennsylvania, Department of Medicine, in 1896, died in Philadelphia from tuberculosis, on March 8, aged 41 years.

Dr. Edgar Pearl Ward of St. Louis, Mo., a graduate of the Marion Sims College of Medicine, St. Louis, in 1894, formerly professor of embryology and obstetrics in the American Medical College, St. Louis, and a member of the St. Louis Medical Society, the Tri-State Medical Society, and the Academy of Medicine of Chicago, who had done considerable research work on tuberculosis, died at his home on February 22, aged 46 years.

Dr. John W. Leonard of St. Joseph, Mo., a graduate of the Medical College of Ohio, Cincinnati, in 1886, died on February 24, after a long illness, aged 50 years.

## Obituary.

### ALGERNON THOMAS BRISTOW, M.D.

BROOKLYN, NEW YORK.

Dr. A. T. Bristow, one of the leading surgeons of this city and editor of the *New York State Journal of Medicine,* died at his home on March 26, of septicemia following a punctured wound of the finger received during an operation. Dr. Bristow was born in Richmond, England, November 29, 1851, and was brought by his parents to this country in early childhood. He was a graduate in arts of Yale College in 1873, and in medicine of the College of Physicians and Surgeons, New York, in 1876. After graduation he began the practice of his profession in Brooklyn where he soon won an enviable reputation as a skilful surgeon and a learned and sympathetic physician.

Dr. Bristow was a member of the Kings County and the New York State Medical Societies, of the American Medical Association, of the American Surgical Association, of the New York Academy of Medicine, of the American Academy of Medicine, and of the Brooklyn Medical, Surgical, and Pathological Societies. He was attending surgeon to the Kings County, St. John's, and Long Island College Hospitals, and consulting surgeon to the Long Island State, Swedish, Coney Island, and Bushwick Hospitals.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

DEFENCE OF RESEARCH—UNILATERAL RENAL LESIONS —CERVICAL RIBS—DEATHS FROM ELECTRICITY— OBITUARY.

London, March 7, 1913.

What do you think of a public lecture as a means of popularizing the defence of research? It does not look to me a promising subject, but the society devoted to this defence arranged for one by Dr. F. M. Sandwith who, with the aid of lantern slides, achieved success on Tuesday by comparing "Ancient and Modern Surgery." He started early, his first slide being a picture of the most ancient doctor of which tradition tells, physician to a Pharaoh of the fifth dynasty about 6,000 years ago. Then there were photographs of splints found in the Nubian deserts resembling those now in use, the fastenings being with the reef knots. Bandages, too, were folded as at the present day. Palm fibre served for the cotton wool and fine linen for gauze. Coming down to the sixteenth century, the lecturer spoke of Paré as a soldier-surgeon of the best type, who never arrogated to himself the power of healing, but wrote as to one of his cases, "I dressed his wounds, God cured him." Paré was also said to have discontinued the practice of pouring boiling oil into shot wounds, and to have introduced ligature of arteries instead of cauterizing the stump after amputations. Photographs were also shown of the old plan of pulley-reduction of dislocations. Paracelsus, said Dr. Sandwith, was a defender of research, urged his students to study patients and reject the idea that a pig and a man were alike inside, but to see by dissecting. Paracelsus had been called the medical Luther, as he burned the works of Galen, as Luther did the Papal bull. Calvin's persecution of Servetus was the next subject, followed by portraits of Vesalius, who advocated dissection; King Henry IV touching for the evil; Hunter, who wrote to Jenner when crossed in love, "Cheer up, man, forget her. I will employ you with hedgehogs," and of Sir J. Paget, who warned clerics not to interfere with vivisection and surgery lest the time might come when doctors might tell them things they ought to know. Now, remarked the lecturer, the arch enemy of the medical profession turns on the Church in Wales. He concluded with a comparison of operating theaters before and after Lister's work. The chairman, Mr. Stephen Paget, then appealed for help for the defence of Research Society. I hope he may have a response equal to his expectations.

"Unilateral Renal Lesions" was the title of a paper read on the 24th ult. at the Medical Society of London by Mr. Ralph Thompson. He had collected from the records of three hospitals 23 cases of "solitary kidney," out of 13,505 autopsies, all of which he said had been read through, no reliance being placed on indices. This commendable industry gives confidence to the accuracy of his statement of the facts. In only two cases was disease or mechanical injury found in a solitary kidney. Some cases of supposed single were found to be instances of double kidney. He was assured by Messrs. Dunn, Steward, and Rowlands that they had never seen a case of double ureter, although Dr. Rolleston had estimated such a condition as occurring in 1 per cent. Dr. Turnbull met it in 1 in 150 autopsies in the London Hospital. Mr. Thompson showed a specimen with aberrant vessels. Of injuries he found 19 to the left, 22 to the right, and only 3 to both kidneys. Of ascending inflammation there were 135 bilateral and 38 unilateral cases. Unilateral hydronephrosis was recorded in 52 cases on the left and 44 on the right side. Of hydronephrosis with granular kidney there were 3 bilateral and 7 unilateral, all on the left side. Attention was drawn to tuberculous peritonitis and other lesions which might cause pressure on the ureters or constrict them by fibrous bands. In one operation Mr. Thompson found such a band and divided it. The question had been raised as to the other kidney when nephrectomy was proposed for tuberculous disease. Mr. Thompson found at three hospitals the autopsies of renal tuberculosis were 37 unilateral to 74 bilateral; in the former the right was affected as 13, to the left 5. Pyelonephritis and bacilluria were more common on the right side. Anatomical conditions were mentioned as probably conducing to this.

Mr. T. Walker appreciated the facts brought forward as highly interesting and important. They had a two-fold aspect—clinical and pathological. The pathologist was pessimistic as he looked at the final stage of a disease. But Mr. Thompson's paper rather dealt with ante-mortem pathology. There was a mass of clinical surgical evidence that renal tuberculosis in its early stage was unilateral, and many cases therefore could be cured by nephrectomy at that stage.

The clinical section of the Royal Society of Medicine well sustains the reputation for vigorous work of the "old clinical" before the amalgamation. At the last meeting the material was as abundant as ever, and, indeed, some members say, much more. The subject was "Cervical Ribs," of which probably more cases were exhibited than any one had had the opportunity of seeing at one time. There were a dozen present. The discussion was opened by Dr. F. Wood-Jones by tracing the development of the ribless neck and loins to the perfection of the pelvic and pectoral limbs. This might be seen in the growth of the embryo in which an antagonism was manifested between aborted costal elements and a limb plexus. To pressure of nerve trunks was attributed atrophy of cervical ribs. The rapid growth of the brachial is seen in the anomalies occasioned by variations met with from the normal position. Thus, if the plexus is lower by one vertebra—a variation not very rare—the first thoracic rib may be badly developed, and give rise to the symptoms met with in connection with cervical ribs. Dr. Wood-Jones attributed the groove on the upper surface of the first rib to pressure by the first thoracic nerve. The symptoms of the cases, too, were to be accounted for by pressure—the sensory and muscular ones by that on the lowest cord of the plexus; the vascular ones being brought about by the resulting changes in the vessels of the arms. The symptoms come on late because the clavicle takes a lower slope as adolescence comes on, and more in adult life. This is more marked in women. As to treatment, operation was agreed by all to be the only means of cure, which it effects in about half the cases, the other half being much relieved. The method of operating, and other surgical points, were discussed by Drs. Sargent, S. A. H. Wilson, and F. Buzzard, and W. Thorburn.

Continuing his Goulotonian lectures at the Col-

lege of Physicians, Dr. Jex-Blake remarked on the small fraction of those struck by lightning who died and added that many apparently fatal cases were curable. Then he spoke of safeguards, enumerating many from Roman times to the present, which the people had believed in. It was curious in these days of vaccine therapy to notice that the Zulus and Kaffirs inoculated themselves with the blood of animals killed by lightning. Of more reasonable precautions the lecturer said windows, doors, and air currents should be avoided, and it was better to keep away from the fireplace, for if the chimney should be struck the contents would be blown out. In the open one should not go near wire, crowds of people or animals or isolated trees, especially the oak. Yet forests are but seldom struck. It is safer to lie down than stand; an umbrella should not be raised. Treatment was artificial respiration to be kept up until the reality of death had been proved by the onset of rigor. The lecturer thought the prone position best, though he admitted that many authorities preferred Sylvester's method. The important thing is to set to work without a moment's delay. This has always been insisted on, but equally important is it to continue the artificial respiration until it is quite certain that death has taken place. The onset of rigor mortis or the cooling of the body must be the evidence insisted on. In reference to the victims of electric shocks, the majority of these accidents occur in workshops or other places where skilled assistance is not present and the simplest plan must be immediately adopted while such assistance is being sought. Other possible modes of treatment were mentioned as having been tried but which should only be attempted by experts and their aid was seldom available and so far the records that had been published were not encouraging but rather pointed to the need of further investigation.

The Town Council of Cheltenham has resolved to open subscription for a fund to commemorate Dr. E. A. Wilson, who perished in the Scott Antarctic expedition. He was a native of the town, where his father, Dr. E. T. Wilson, is now the senior medical practitioner. Probably the memorial will in some form be associated with the local hospital.

Sir C. Colvin-Smith, M.D., K.C.B., K.H.S., died on March 1st in his eighty-fourth year. An Aberdeen graduate, he joined the Madras army in 1851. He was P. M. O. with the Indian contingent in the Egyptian campaign, present at Tel-el-Kebir, as well as the taking of Zaguzig the same day. He was the recipient of a good service pension, medal and clasp for the Burmese war, and for the Indian mutiny; also for the Egyptian campaign with Khedive's star and the order of the Osmanish.

Deputy Inspector-General George Saunders, M.D., C.B., died yesterday in his ninetieth year. He served in the Crimea and through the epidemic of fever in China in 1865, after which he was made a C.B. in recognition of his arduous labors.

Surgeon-General H. Skey Muir, C.B., late Army Medical Staff, died suddenly yesterday at the age of 71. He qualified at the R. C. S. in 1863.

Dr. E. Henderson, F.R.C.S., M.D. Edin., late surgeon to the General Hospital, Shanghai, and municipal medical officer and health officer there, has died here at the age of 72.

Dr. F. P. Weaver, J.P., who graduated with honors at the London University M.B. 1860, M.D. 1861, has died at the age of 79. He became M.R.C.P. in 1893.

## AUDI ALTERAM PARTEM.

To the Editor of the Medical Record:

Sir:—In a recent number of the Medical Record it is stated editorially that "The *Sun* of this city, a journal usually as well informed as it is fair-minded in matters medical, uses the Friedmann episode as a text for some hard sayings regarding the medical profession." Your criticism of the statement of the *Sun* regarding "the violent opposition of the medical press" I do not venture to answer because of your far better opportunity and owing to my reading not being extensive. Moreover, I have read no violent opposition statements in the Medical Record. You are certainly right in criticising all commercial methods. I would, however, ask the privilege to point out wherein you have, by reason of hasty reading probably, missed the meaning of a portion of the editorial article which you criticise. I have followed with interest the reported doings of Dr. Friedmann, whose claim I in nowise share. I noted that the public was in a state of ferment owing to press reports, dissatisfaction with the misconstrued opposition of the medical fraternity was heard and read everywhere, and it was as usual falsely attributed to professional jealousy. What more natural for one who has the interests of his colleagues at heart no less than that of suffering humanity to write the following, after defending the action of the medical societies whom he characterizes as "watch dogs of medical ethics":

"There is a tradition in medicine that very *properly* bars secret remedial methods from adoption by physicians. In the olden time, when medicine was practically an eleemosynary profession, temples were the clinics and priests the doctors. Hippocrates, the Father of Medicine, brought to its study and practice a wealth of good sense that inured to the benefit of patient and doctor alike, removing much of the existing mysticism while insisting upon the sacred character of the physician's calling. The beneficent influence of the 'Hippocratic oath' happily still sways the medical mind; and to this fact must be attributed the *seeming* indifference of the *true* physician to the interests of the patient when a question of ethics is involved."

If these words are "a slur upon the medical profession" I shall have to renew my study of the English language. Your strictures would have been quite warranted had three little words, which I have put in italics, been omitted from this dignified statement. If aught in this editorial can be construed into "hard sayings regarding the medical profession" it must be the first among hundreds I have read that does not express the sentiments of the following excerpt from one of the same writer's articles: "I shall continue as far as in me lies to further and protect the interests of the calling to which my whole life has been devoted, and I know no more effective way of accomplishing this aim than by unsigned editorials in a metropolitan newspaper having a large and discriminating clientele." Among the large number of medical editorials I have read in the *Sun* there is not one that does not breathe the spirit of these lines. Moreover, I have never read any defense or approval, much less advocacy, of the Friedmann serum in the *Sun*—nothing more than a plea for that fairness which appears about to be meted out.

7. Ball-Valve Apparatus for the Administration of Salvarsan. L. L. Albert.

1. **Ureteral Obstruction.**—B. Tenney states that two symptoms appear in almost every condition which obstructs a ureter. One is pain between the point of obstruction and the tenth rib, on the obstructed side. The pain varies from a dull ache to agony and may produce anything from nervous irritability to vomiting and unconsciousness. This pain is sometimes increased by motion, as in stone cases, sometimes brought on by a change from the horizontal to the upright position, as in cases with ureteral kink, and sometimes appears without regard to either, as in pus or bleeding kidneys when the patient's pain comes and goes quickly with the passage of some fibrin mass through the ureter. Pain is present when there is back pressure in the kidney and may be associated with vomiting and fever, or it may be associated with vomiting and a normal temperature, or there may be subnormal temperature. The pain is said to radiate along the affected side down to the penis or vagina or leg, but the author's patients have had most of their pain in the back in the region of the twelfth rib. Radiation—unless pelvic pain be considered such—has been uncommon in the author's cases. Cases with pain on the unaffected side have been reported on good authority. The pain may be recent or of long standing. Pain is what the patient describes without examination. Tenderness may correspond in location or differ. When a patient is in pain from ureteral obstruction he is also tender over the affected kidney. When he is not in pain the tenderness may and often does disappear. In women the ureteral insertion, which can almost always be felt through the vagina, will be found sensitive if there is infection behind a point of obstruction, and often while the infection remains a bacteriuria. The other constant symptom is an alteration from the normal habits of urination. One may find increased frequency, urgency, incontinence, or the necessity of repeated attempts before the desire passes away. The presence of any one of these symptoms is a plain warning that something is wrong in the urinary tract—not necessarily in the kidney—and calls for further study.

2. **Conservative Treatment of Convulsions in Pregnancy.**—C. M. Green believes that it is better to postpone active surgical treatment of this condition for a reasonable time until by active eliminative measures the toxemic gravida is better prepared to withstand the added strain of delivery. He also believes that when the shock and truama of the *accouchement forcé* are hastily imposed upon a nervous system already reacting to toxemic irritation, the *coup de grâce* is not infrequently given to women who under more conservative treatment might recover. Moreover, under successfully applied eliminative therapeusis, the cervix and lower uterine segment often soften and expand to a degree that the woman speedily delivers herself under the usually exaggerated uterine contractions of the convulsive attack, or sufficiently to permit delivery without undue shock or injury. After the cervix is softened and somewhat dilated, it is not difficult to procure by digital dilatation a sufficient expansion for the delivery of the small, nonviable fetus, making use of embryotomy, if necessary; and when the fetus is developed to a viable age and is alive, the use of a suitable hydrostatic rubber bag very generally results in a dilatation sufficient to permit safe delivery by forceps or podalic version.

3. **Prevention of Foot Strain.**—R. B. Osgood notes that there exists no definite relationship between the height of an arch and the strength of a foot. The highest arches are often found in the least stable feet and the lowest among savage tribes whose foot-action is most perfect. Furthermore it is often difficult to determine from inspection and palpation alone the potentiality of strain in symptomless feet, and yet in a certain class of cases the ability to do this may be of considerable importance. The author, in conjunction with H. Legg, made a study of the comparative strength of the abductor and adductor groups of the foot, using for this purpose a simple apparatus. The average ratio of the adductor pull to the abductor pull in normal feet was found to be 10 to 8.2 in favor of the adductors. In pronated feet without symptoms the ratio was 10 to 10.5 in favor of the abductors. In pronated foot with symptoms it was 10 to 10.8 in favor of abductors. In cases of acute foot strain with valgus the ratio was 10 to 12.2 in favor of abductors. The author's experiments were carried out on nurses in the Massachusetts General Hospital. All the probationers were examined during their first few weeks of hospital life. They had explained to them the reasons for wearing during their working hours proper shoes. Lasts suitable to their individual needs with and without Thomas' heels were prescribed. Eighty-four of 133 taken chronologically and followed for at least a year were considered to need advice. The simple cases of strain and those who were believed to possess the potential of strain were thus treated. Among the students of Wellesley College a surprisingly small number are able to take a walk for a considerable distance without general and foot fatigue. There is a very general tendency to vicious shoes of the pointed type.

4. **Typhoid Vaccination.**—J. H. Young summarizes his study of this subject as follows: Typhoid vaccine as a prophylactic provides almost certain protection from typhoid fever. As a therapeutic agent in active typhoid it is still in the experimental stage. Not a sufficient number of cases have been studied to enable one to draw definite conclusions. The results so far obtained, however, are favorable. Typhoid vaccine as a therapeutic agent in chronic typhoid carriers, while it does not offer a certain cure, is the method of treatment that has given the best results.

12. Appendicitis or Not Appendicitis? H. A. Schatz.

1. **Acidosis.**—W. S. Gordon, after reviewing the literature of this subject concludes that the processes concerned in producing acidosis are not thoroughly understood, and that they result from a disturbed metabolism due to various pathological conditions. While acetonemia may appear with carbohydrate starvation and disappear with a corresponding regulation of the diet, it does occur on a full carbohydrate diet. Even in the former case other preexisting factors may be operative. Excessive urea formation may precede the appearance of acetone. The gravity of the condition may be out of pro-

portion to the amount of acetone in the urine; and while a large number of cases of acetonemia are relieved, even when unrecognized and untreated, the toxemia is frequently of serious import. Its occurrence with alkaline and phosphatic urine should not be overlooked. It is evident, also, that the nausea, vomiting, and consequent abstinence from food which are often correctly supposed to cause acidosis may frequently be results instead of causes, and that, so far as symptoms and treatment are concerned, the toxemia should in such cases be regarded as a primary and not as a secondary or incidental disorder. Furthermore, it should not be forgotten that the symptoms of acidosis may be erroneously attributed to other morbid states. Especially in pregnancy should one be on the watch for a toxemia due directly to acetone and not accounted for by kidney involvement or the retention of urea. The importance of routine examinations of the urine is appparent, lest one be caught napping and find oneself confronted by a grave and unsuspected complication.

2. **Blood and Sputum in Lobar Pneumonia.**—R. C. Rosenberger and C. V. Dorworth conclude from their investigations that as the cultures were taken upon varying days from the time of onset of disease, it cannot be said that one would be more likely to find an organism at one time before the crisis than at another. The finding of an organism in a culture taken after the crisis or beginning of lysis is, in the authors' findings, rare. This finding is, however, possible. This is probably due to the development of "anti" substances during the growth of pneumococci, to the fact that symbiosis has ceased to exist, and to the fact that the organism dies out. In one series diagnosticated as lobar pneumonia organisms other than the pneumococcus were found in the blood. These other organisms include the staphylococcus, the streptococcus, and in one case an organism morphologically and culturally resembling *Bacillus typhosus*. It is possible that in some few cases the staphylococcus came from the skin. The prognosis of uncomplicated lobar pneumonia is not altered by obtaining the pneumococcus in culture. It is noted that in this series of cases most of the patients having the lesion on the left side recovered, while with one exception every patient having a lesion upon the right side died. This may have been, however, only a coincidence. Of the four cases coming from the alcoholic ward three died.

4. **Disease of the Nasal Accessory Cavities.**—S. Oppenheimer concludes that in the presence of chronic osseous changes, or the development of active eye symptoms or endocranial complications, radical operation is imperative—and one should not temporize with anything less. In combined frontal and ethmoidal suppuration, with more or less polypoid degenerative changes of the middle turbinal, external radical operation alone will effect a permanent cure. In frontal and maxillary sinusitis, where there is reason to believe that intercellular septa or irregular partitions exist within the sinus, it is impossible to obtain a satisfactory result other than with large external openings which will allow the thorough removal of such septa and the diseased mucous membrane. If, however, free drainage is present, and there are no signs of ill effect on the general health and only an occasional headache is complained of and the patient can be kept under observation, the risks of radical operation more than counterbalance the advantages. Obliteration of the infected cavity in its entirety is the ideal aimed at in radical procedures. If that is not accomplished a cavity remains that may again become infected, with a repetition of the former morbid process. Previous, therefore, to a radical operation, especially upon the frontal sinus, the patient should be informed of the possible final results of the operative procedure, that such an operation, like many others, is not always successful, and that it may be attended with serious consequences; and, finally, that it is not to be classed otherwise than as a serious major operation.

7. **Extrasystoles.**—S. Neuhof notes that the recognition of extrasystoles by ordinary clinical methods of examination is usually easy. Painful sensations in the chest accompanying extrasystoles are infrequent. Depending upon the underlying cause, patients with this type of arrhythmia may or may not require treatment. When the cardiac condition calls for digitalis or allied drugs, extrasystoles offer no contraindication to their use. When viewed as part of the clinical syndrome, extrasystoles may sometimes be of prognostic importance. Extrasystoles may be forerunners of more severe types of arrhythmia, particularly of tachycardia and auricular fibrillation.

10. **Treatment of Hopeless Cases of Tuberculosis.**—M. W. McDuffie presents a preliminary report of the work in Ward Q of the Metropolitan Hospital of New York City during the past year in the treatment of so-called hopeless cases of pulmonary tuberculosis. There were 500 patients under observation, and the following therapeutic agents were employed: Mercury succinimide, mercury bichloride, mercury biniodide, arsenic troxide, salvarsan, mineralization, oils, Sherman's vaccines (letter P), combined bacterial vaccines (Van Cott), Schafer's vaccine or filtrate, Schafer's tuberculosis vaccine or filtrate, Cocheu's vaccine or filtrate, Duncan's autotherapy filtrate, tuberculin by mouth, tuberculin injections, antistreptococcus serum, quinine, baptisia, formaldehyde solution, salicylic acid, salicin, sodium salicylate, guaiacol, and vanadium, a total of twenty-six different forms of treatment. The author concludes from his observations that the treatment depends to a marked degree upon the stage of the disease. The tubercle bacilli cause less trouble and are more easily eliminated than the complicating mixed infection. All stages have the mixed infection to contend with. Immunity should be produced during childhood by the avoidance of excesses and right living. In freeing the organism of the germs, guaiacol mixture intravenously has given the best results up to the present time. To make the soil unfavorable for the bacterial growth, tuberculin is of value in the early stages; it is of no value in the later stages. Vanadium, with which the author is now working, is regarded by the latter as a useful means of making the soil unfavorable for growth in the last stages and possibly in all stages.

1. **The Surgery of Mammary Cancer.**—J. B. Deaver believes that the favorable time for operation is when there is a symptomless, freely movable lump in the breast, but patients are rarely seen at this stage. In the author's series both malignant and benign tumors occurred most

frequently in the upper and outer portions of the gland. Enlarged axillary lymph nodes do not necessarily mean malignancy; they are non-malignant in 6.5 per cent. of all cases. The absence of attachment to the pectoral fascia does not indicate non-involvement of the fascia, which, as well as the muscles and intramuscular lymphatics, may be involved before adhesion occurs. Distant metastases are probably accounted for by blood infection. The author has seen late apparent recurrence twenty years after removal of a cancerous breast. The *x*-ray has no place in the treatment of operable cancer, but is the only available measure in inoperable cases and in the prevention of a post-operative recurrence, which, from position or otherwise, cannot be further operated on. With the radical operation the average primary mortality is about 1 per cent. In the author's total of 534 cases, malignant and benign, there were only three deaths after operation. As regards cure, approximately one in five is permanently relieved of the disease by the radical operation, though the inability to secure reliable data makes even this percentage questionable. This percentage would probably be materially lessened if the patients with cases pronounced inoperable, whose names do not appear on hospital records, were included in the statistics. These results are highly disappointing unless compared with the results of past decades. When popular opinion demands immediate operation on the discovery of a lump in the breast; when physicians are taught to think of breast tumors in terms of operability; and when misguided humanitarianism no longer prompts the surgeon to attempt injudicious operations, the present lack of faith in the surgery of this disease will give way to a healthy optimism.

4. **Arteriosclerosis.**—L. F. Bishop urges the importance of the periodical examination of supposedly healthy persons past middle life. Persons with a tendency to circulatory disease should undergo regular courses of treatment such as those given in certain European health resorts. The author also counsels against the abuse of certain drugs, such as saline laxatives and mineral waters, which may upset the body metabolism. Castor oil is the best remedy for those threatened with amino-acid poisoning.

7. **A Preparalytic Symptom of Poliomyelitis.**—J. A. Colliver refers to what he regards as a new symptom in this condition. This symptom is a peculiar twitching, tremulous or convulsive movement of certain groups of muscles lasting from a few seconds to less than a minute. The amplitude of vibration is greater than a tremor, not so constant and long as a convulsion, and more regular than mere twitching, yet it has some elements of all of these. It usually affects a part or whole of one or more limbs, the face or jaw, but it may sometimes affect the whole body. The symptom may easily be overlooked in the beginning as it usually lasts less than a second and unless the patient is disturbed does not recur oftener than every hour or so. Later the duration of the spells lengthens to a few seconds, recurring also at shorter intervals. This condition is often accompanied by a peculiar cry similar to that of hydrocephalus. At times there is a slight convulsive movement, just like a chill, as mothers say, during which time the child is apparently unconscious with eyes set for a few seconds. This brief unconsciousness may occur without noticeable convulsive movements. The phenomenon resembles those found in light cases of strychnine poisoning except that the tetanic contractions are not general and do not last for a long time. This symptom seems to be similar to the infection neuroses described by neurologists, of which tetany and chorea are good examples. It is not unreasonable to suppose that the presence of the virus of poliomyelitis may bring about effects similar to those of chorea and tetany.

16. **Irrigation of Spinal Canal in Meningitis.**—D. J. Hirsch states that the mortality of cerebrospinal meningitis is still too high, and in view of the inaccessibility of the diplococci to the serum in some cases, he thinks that it would be advisable to modify Robb's procedure and irrigate in all cases, whether the fluid is purulent or not. The objects of irrigation are the removal of a large number of cocci and the preparation of the field for the reception of the curative serum, which would more than compensate for the loss of a few leucocytes. The technique is described as follows: Remove from 30 to 40 c.c. of fluid by lumbar puncture; then with a small syringe, using gentle pressure, introduce 30 c.c. of normal salt solution, 100° F., into the canal; allow this to return; repeat this three times in those cases in which the fluid is cloudy, and, in the purulent cases, repeat the procedure until the fluid returns clear. The canal should then be clear, and the serum better able to do its work. Two cases thus treated are reported, and the author thinks the treatment will be found of benefit in the treatment of meningitis.

6. Case of Subcortical Cerebral Tumor, Tuberculous in Nature, Removed by Operation; Recovery. G. Hall.
7. The Treatment of Pulmonary Tuberculosis. N. D. Bardswell.

2. **Surgery of the Thyroid.**—J. Berry is of the opinion that exophthalmic goiter is a disease of which the treatment, whenever possible, should be carried out jointly by the physician and surgeon. He ventures to ask whether the time has not arrived when physicians should recognize that they can do little or nothing for its actual cure, but that they can do much to get the patients into a proper condition for operation. On the other hand, the surgeon should realize the value of medical treatment as a preliminary to surgical interference, and should remember that there are stages of the disease during which the patient should be entirely in the physician's hands. It is common to hear of patients, who might be much benefited by operation, being kept indefinitely under medical treatment in out-patient departments, or intermittently in the medical wards, before a surgeon is even asked to see them, and when he is called in it is often to some desperately bad case on which he is expected to operate immediately as a last resort. In summing up our certain knowledge as to the dangers and advantages of the operative treatment of Graves' disease, the author believes that one may say that operations upon cases of exophthalmic goiter are more dangerous than similar operations for most other kinds of goiter, but that the dangers may, however, be greatly reduced by careful attention to details, especially in the selection of cases for operation, and in the choice of the time at which the operation should be performed, in the preliminary treatment of the patient, in the methods of operating, and in the after-treatment. That much benefit nearly always follows operation is undoubted, and that cure does sometimes follow as a direct result of the operation, especially in early and slight cases, there can be equally little doubt. Even in really bad cases, in which operation must involve serious risk, so much improvement often results that operation should not be too lightly put aside.

3. **Percussion and Auscultation.**—F. Müller states that the normal lung responds on an average with the same low sound, if its fundamental tone is evoked by percussion, or by the stretching of inspiration, or by the voice. The fundamental tones of the cavities of the abdomen have a higher rate of vibration: the fundamental tone of the bronchi (bronchial breathing, consonant râles) takes its place between c′ and c″; and the metallic sound is characterized by the highest overtones. The normal heart sounds and the murmurs of valvular diseases show the

same pitch as vesicular breathing—*i.e.* between 60 and 160 waves in the second—and therefore it is sometimes very difficult to distinguish systolic vesicular breathing from valvular murmurs. Some physicians have tried to exaggerate the technical refinement of percussion and auscultation to artistic virtuosity, and to draw the keenest diagnostic conclusions from its application. These methods of examination are the object not so much of artistic skill, as of scientific understanding, and there is necessary first a solid scientific foundation and criticism. A comparison between the results of percussion and auscultation with the results of the Röntgen ray exploration or the necropsy finding often shows that one has to be very careful in drawing conclusions from the physical examination, and that this does not grant as conclusive proof concerning the conditions of the inner organs as many have imagined.

5. **Fatal Hematemesis in Hepatic Syphilis.**—D. E. Core reports a case which represents an important group of cases of hepatic syphilis, in which the disease resembles ordinary cirrhosis of the liver. The symptoms are usually those of pain in the right hypochondrium, with more or less gastric disturbances, occasional hematemesis, and ascites. Jaundice is rare in these cases of hepatic cirrhosis, and according to Hale White so also is ascites. On examination of the abdomen the liver and spleen are found to be enlarged and firm. Pain generally is a prominent symptom, owing to the perihepatitis and perisplenitis, and although in the case reported by the author there appears to have been a remarkable absence of this symptom, yet from the appearance post-mortem of the liver and spleen, which were unduly adherent to the diaphragm, some pain almost certainly must have been present at one time or another. The diagnoses of these cases rests on the preponderance of syphilis over alcohol in the history, and the relief of symptoms by antisyphilitic treatment. Rolleston has pointed out that the routine treatment of ordinary alcoholic cirrhosis consists of potassium idodide, and that cases recorded of cure in this disease are, in all probability, cases of syphilis of the liver. Two further points of interest in the author's case were, firstly, the absence of any blood in the stomach contents or upper part of the small intestine, and the absence of any bleeding point to be made out post-mortem. Death in this case was due to acute cerebral anemia, and it is probable that the patient made some sudden movement or exerted himself in some way so as to cause the acute symptoms that immediately preceded death without there being any fresh bleeding. The absence of any apparent breach in the gastric mucosa or enlarged esophageal veins is most likely due to the collapse that must have occurred in any such veins that may have existed; it is a matter of common knowledge that it is often exceedingly difficult to demonstrate post-mortem esophageal varices in subjects that have died from sudden and profuse hematemesis owing to the empty and collapsed condition

---

1. Recent Advances in the Diagnosis, Prognosis, and Treatment of Heart Disease: the Polygraph. F. W. Price.
2. Certain Physical Signs of Myocardial Involvement. T. Lewis.
3. Manifestations of a Healthy Heart. W. B. Thorne.
4. The Ventricular Rate in Complete Heart-block. A. E. Naish.
5. The Auricle in Mitral Stenosis. D. W. Samways.
6. Death by Electric Currents and by Lightning. A. J. Jex-Blake.

1. **Recent Advances in the Study of Heart Disease.**—F. W. Price subdivides all cases of irregularity, apart from comparatively rare exceptions, into five groups. They are: (1) What is called sinus irregularity, (2) irregularity due to what are called extra-systoles, (3) irregularity due to depressed conductivity, (4) irregularity due to the pulsus alternans, and (5) what may be called complete irregularity. Sinus irregularity is characterized by a variation in the length of the diastolic period of the different cardiac cycles, the systolic period remaining constant. By extra-systole is meant a premature contraction of the auricle, or of the ventricle, or of both auricle and ventricle together, while the fundamental or sinus rhythm is maintained. It is of very great importance to be able to recognize the presence of extra-systoles, because they constitute one of the most frequent causes of irregularity of the pulse, and they may be accompanied by subjective phenomena which cause the patient much distress and alarm. Digitalis should not be administered as a mere rule of thumb in all cases of cardiac failure. In any given case, whether there is mitral disease, aortic disease, or disease of the myocardium, one should determine whether auricular fibrillation is present or not. If fibrillation is present and is accompanied by a very rapid pulse, whatever the lesion in most cases, and especially in those patients with a history of rheumatism or chorea, one has a therapeutic agency of wonderful potency which can establish and maintain control of the heart rate. The administration of the drug is followed by a rapid fall in the pulse rate and a concomitant improvement in the general symptoms. Two exceptions are: (1) Cases of cardiosclerosis in which the degenerative change is so widespread that little healthy muscle remains: and (2) cases in which there is pyrexia. When pyrexia is present, apparently the response to digitalis is as a rule very slight, if at all, whether auricular fibrillation is present or not. It is well to begin with a dram of the tincture per day, or in urgent cases with even 1½ or 2 drams per day, and continue until there is nausea or vomiting, diarrhea, headache, an unduly slow pulse, or what is called "coupling of the beats." Coupling of the beats is a danger signal. One should either stop the drug for a few days or diminish the dose. Usually a reaction is obtained within a week, sometimes in a few days. Then the drug should be stopped until the symptoms have passed away. As a rule the patient relapses. The indication then is to find out what dose suits him best—that is, the dose sufficient to control the heart without producing toxic symptoms.

2. **Signs of Myocardial Involvement.**—T. Lewis emphasizes the fact that the development of heart block during the course of an acute rheumatic illness is an evidence of myocardial involvement, not necessarily limited to the auriculoventricular bundle, but almost certainly spreading to a greater or lesser extent beyond it. The sensitive tract, when implicated, is responsible for signs which, relative to the extent of the lesion, are far more conspicuous than those yielded by implication of the general mass of the ventricular muscle. The majority of the rheumatic illnesses end in recovery, and this is one of the chief difficulties in studying them. One is compelled largely to judge of the events which have occurred in milder attacks from the findings in those which are severe.

6. **Death by Electric Currents.**—A. J. Jex-Blake states that in the vast majority of cases death by electric currents is due to accident; but in Italy both suicide and murder by electricity have been attempted, the former with success. The death of human beings may be brought about by electric currents in several different ways. There is no doubt that it might be due to prolonged tetanus of the muscles, which could prevent the performance of respiratory movements, and so lead to death by asphyxia after some minutes. But the author is not able to find that it ever has come about in this way as a matter of fact, the victim always being able either to break the contact and interrupt the passage of the current for himself, or to call for help and get the contact broken by somebody else before asphyxia has occurred in this way. In man primary heart failure is undoubtedly the commonest mode of death by electric currents. The experiments on animals show that such deaths are due to fibrillation of the ventricles of the heart. This fibrillation has been seen occurring in the

hearts of two criminals electrocuted and examined immediately after death. Death by failure of the respiration while the heart continues to beat, brought about by nervous inhibition, or by failure of both heart and respiration together, is probably not common in man. Brief reference is made to the fact that a good many cases have been recorded in which the victim of an electric accident has died after a few days or weeks from complications (shock, gangrene, suppuration, exhaustion following extensive amputations) arising out of the injuries caused by the electric current.

**Internal Secretions and the Nervous System.**—Münzer's serial article, one installment of which has already appeared in the MEDICAL RECORD, ends with the following summary: Both physiology and pathology teach us that the functions of the blood glands are intimately associated with the activity of the nervous system. It is probable that the products of the blood glands act solely upon the nervous system in producing their characteristic effects. We may generalize to the extent of stating that blood gland activity is expressed by nervous reaction. This does not imply that all nervous structures are uniformly influenced; for as far as we know there are preferential activities—on the one hand involving the brain and possibly the cord, and on the other the sympathetic. The multiglandular system, involving the combined action of the ductless glands, comes into direct relationship with the nervous system through the influence exerted by the internal secretions on the tonus of the sympathetic nerves. The secretion of an individual gland exerts a specific activity on a definite territory of the nervous system. As a consequence of this specificity, a classification may be built up in regard to the various activities of the secretions upon the various activities of the nervous system—sympathicotonic, spinotonic, polytonic. The assumption of a regulation of tonus of various secretions of the nervous system may lead to definite results from the therapeutic viewpoint.

**Statistics of Gastric Resection.**—Weil sums up the results of 157 operations of this sort performed within the past five and a half years. He concludes that as a palliative in cancer cases, the operation of resection is much more serviceable in cancer of the stomach than gastroenterostomy; that every case of positive recovery thus attained represents an actual advance; that despite the small proportion of recoveries, the number is large if we consider that 15,000 persons die annually in Germany of cancer of the stomach. A comparison of the author's figures in the Breslau Clinic with those of his predecessor show that the operative mortality has decreased; that the percentage of permanent cures is unaltered; and that the percentage of diagnostic cases operated upon not only does not increase but actually diminishes.

**The Active Principle in Biochemical Radiation Reaction.**—Schwarz sums up as follows: Thorium-X solution, which contains neither ozone nor hydrogen peroxide in demonstrable quantities—as shown by the starch-potassic iodide paper—causes after 24 hours an energetic cleavage of lutein and lecithin in egg yolk. Even highly concentrated solutions of hydrogen peroxide (which call forth an intensive browning of the test paper) do not after similar exposure cause such changes. Hence neither ozone nor hydrogen peroxide play any part in these thorium reactions. We know that $H_2O_2$ and various other substances (including lipoids and coloring matters) tend to destroy organic matter, but it does not appear to be justified to refer the peroxide action to Thorium-X or to assume that the latter manifests its activity through the content of $H_2O_2$.

*February 27, 1913.*

**The Duodenal Catheter in the Study of Pylorospasm and the Action of Pancreatic Enzymes in the Nursling.**—Hess of the Public Health Laboratories, New York City, already well known in this field of research, sums up his finds and conclusions as follows: In children up to two years of age it is easy to introduce a simple Nelaton catheter (15 French) through the stomach into the duodenum. This so-called duodenal catheter makes it possible to distinguish between spasm and stenosis of the pylorus—necessarily under control of the fluoroscope and with the understanding that no organic disease is present. In the same classes of cases the catheter may be used for feeding, as in the case of adults. In spasmodic cases the introduction of the sound seems to relax the spastic state. Aside from this practical issue the duodenal catheter has an additional value for scientific research. Its introduction permits the immediate derivation of pancreas secretion, and makes it possible to demonstrate that all three pancreatic ferments, including the diastasic, are present during the first days of life. In children with pedatrophy there appears to be no deficiency in pancreatic secretion, although this condition is usually assumed to exist. In many of these children there is lowered secretion of gastric juice, while the thin, watery intestinal secretion contains all three pancreatic enzymes in full amount save for lipase, which is present only in small quantity. This condition has been variously known as "paralytic pancreas hypersecretion" or "pancreas succhorrhea." Further, in many cases of hypersecretion of the stomach, there is an increased secretion of the pancreas, which is evidently due solely to the excitation of pancreatic juice by the increased activity of the gastric juice. This process is purely physiological. By means of the duodenal sound we may also investigate icterus neonatorum; we may determine whether or not this state is due to congenital obliteration of bile ducts. The sterile gelatine capsule introduced with the catheter may be employed for the withdrawal of intestinal secretion for bacteriological investigation (dysentery, typhoid, etc.). In a single case of suspected typhoid the bacillary fluid was obtained in almost pure culture.

**Causation of Hirschsprung's Disease.**—Meyer sums up an article on this subject as follows: A seemingly sound infant aged 9 months, nourished on ordinary baker's milk, suddenly developed vomiting, constipation, and general malaise. It was then fed upon flour food, but after two weeks developed flour poisoning, in the course of which spasmophilia appeared. Soon afterwards there ensued, as shown by the *x*-ray, a persistent contraction of the sigmoid flexure. There resulted obstipation, gas distention, increased peristalsis, painful spasms in the abdomen and dilatation of the colon. This syndrome was construed as incipient Hirschsprung's disease. The treatment consisted of belladonna, tinct. opii, and Friedenthal's artificial mother's milk. The child recovered after some months.

**Relapsing Fever in Persia.**—Dschunkowsky relates the part played by a domestic "bug" in the causation of this affection. The reputation of this insect is so bad that it is reputed to kill certain aliens. The bugs lurk in plastered walls, from which they emerge to sting sleeping subjects. The local accidents are only itching and redness, yet in a few days fever develops, perhaps with fatal ending. This history can argue only for the existence of a harmless insect acting as a host or intermediary for a fatally infectious parasite. The author's study shows that the "bug" is not a true insect but a tic—the ornithodorus. The particular spirillum inoculated by this tic does not correspond to any known form, but is closely related to several pathogenic spirilla. The conditions of its parasitism have not yet been worked out.

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### ELEMENTARY PRINCIPLES OF LIFE INSURANCE.

*The Life Annuity.*—It is necessary to understand the process of calculating the cost of annuities before it can be demonstrated how the single net premium for life insurance policies is divided into exact equivalent yearly payments to be made during life.

An annuity is a yearly payment of a certain sum of money to a designated person provided such person is alive at the time the payment falls due. If the payment is to be made every year until this person dies, it is termed a life annuity. For example: a life insurance company, in consideration of the payment to it of a specified amount, say $1,000, may enter into a contract to pay a designated annuitant, say $100 on a specified day in each year so long as the annuitant lives. The latter may draw his annuity for many years until he has received much more than the original cost, or he may die after he has collected only a single payment. In either case, the annuity terminates with the death of the annuitant. It naturally follows that a certain sum will purchase a larger income for a man sixty than for one thirty-five.

The net amount to be paid for an annuity in one sum is determined by a mathematical computation based upon the table of mortality, similar to that for ascertaining the net single premium. For example: what is the net amount which the hypothetical company, referred to in previous articles, should charge in a single sum for a life annuity of $1.00 to be paid to every one of the 81,822 members of the company, all at the age of thirty-five years, the first payment to be made immediately on the execution of the contract? The reader is reminded that 81,822 is the number of persons still living at age thirty-five, as given in the mortality table and adopted as the size of the membership of this company.

As each person of the company is to receive $1.00 immediately, it is plain that $81,822.00 will be required at once in order to pay the annuities due at the beginning of the first year.

According to the table, 732 annuitants will die during the first year after receiving but one payment. This leaves 81,090 persons living on the first day of the second year, each of whom should receive $1.00 on that day. The present worth of $81,090, according to the interest tables, at three and a half per cent. for one year, is $78,349.16, the sum which must be on hand in the beginning of the company to pay for the annuities in this group.

Consulting the table once more, it is seen that 74,985 persons will be living at the beginning of the tenth year at age forty-four, requiring the total payment on that day of $74,985. The present worth of this sum at three and a half per cent. for nine years is $55,016.49, the amount which the company must have on hand in the beginning to pay the annuities due on the first day of the tenth year.

Similarly, it is found that $3.00 will be required on the first day of the sixty-first year to pay the annuities of the last three members at age ninety-five, and that the present worth of this sum, payable sixty years hence, is $0.1269.

By working out the sums to be paid in each and every year from the mortality tables, it will be found that the total payments for the sixty-one years will amount to $2,641,518. Further, that the present worth of the sums to be paid out in each and every year will just reach $1,521,707.42. On dividing $1,521,707.42 by 81,822 it will be seen that $18.61 should be contributed by that number of persons at age thirty-five to create an annuity fund sufficient to pay each and every man $1.00 a year as long as he lives, provided the deaths occur as indicated in the mortality table and the funds earn three and a half per cent.

*The Net Annual Premium.*—It has been found that $18.61 paid down in one sum is the exact mathematical equivalent at age thirty-five of the payment of $1.00 at the beginning of each year during life. It has also been determined in a previous article, that the net single premium for $1,000 insurance at age thirty-five, paid in one sum in advance is $370.55. If then, $18.61 is the mathematical equivalent of $1.00 to be paid annually during life, $370.55 must be the mathematical equivalent of as many dollars to be paid during life as $18.61 is contained times in $370.55. The result of this division is $19.91. In other words, $19.91 paid at the beginning of each year during life, is the exact equivalent of the net single premium of $370.55 and is therefore the *net annual premium* of an ordinary life policy of $1,000 at age thirty-five.

It has been the object in this and the preceding articles to present a simple and lucid summary of the process of computing the premium. So far, only the net premium has been considered, so that the question of provision for expenses and contingencies still remains to be adjusted.

*Sufficiency of the Premium.*—It is imperative that a margin of safety be invariably and strictly maintained in adjusting the premiums. It must be taken for granted that the funds will earn more than the rate of interest assumed, never less; also that the mortality will not be greater than that indicated by the table. Experience for many years has demonstrated that the mortality will not exceed the tabular rate. Although the low interest rate and a lower mortality than the tabular rate calls for a higher premium than that required to meet exactly the requirements, this means no hardship to the policyholders as any excess will be returned to them. It would, on the other hand, mean disaster if the funds on hand were found to be insufficient to meet the later payments to the policyholders, an event which would almost surely happen if non-conservative investments were made to secure larger profits and a poor selection of risks resulted in a high mortality.

---

**X-Ray Injuries Not an Accident.**—A writer in the *Augsburger Postzeitung* notes the case of an electrician who was employed for fifteen years in the *x*-ray room of an orthopedic clinic and had suffered from a chronic affection of the skin of the hands and face resulting from constant exposure to the rays. He was finally incapacitated, and applied to his trade union for the indemnity for accidental injury during employment. The union refused such indemnity, stating that the injury complained of was not due to any accident, but was really an occupational disease, not to be indemnified according to the terms of insurance. An appeal to the courts was decided in favor of the union's interpretation of the agreement.—*Zeitschrift für Versicherungs Medizin*, Vol. V, No. 12.

# Book Reviews.

Diseases of Women. By Thomas George Stevens, M.D., B.S. (Lond.); F.R.C.S. (Eng.); M.R.C.P. (Lond.), Obstetric Surgeon, with Charge of Out-Patients, St. Mary's Hospital, Paddington; Surgeon (Gynecological), the Hospital for Women, Soho Square; Physician to In-Patients, Queen Charlotte's Lying-In Hospital; Examiner to the Central Midwives Board. With 202 illustrations. Price $5.50. London: University of London Press; Hodder & Stoughton and Henry Frowde, 1913.

The author states that this book is the practical outcome of ten years' experience in teaching gynecology to students. The result, as expressed in this volume, is a certain success. The entire work, placed on a sound pathological basis as far as possible, is written in a careful style and the subjects are discussed in a simple, convincing manner. The chapter on Diagnosis shows, aside from the medical standpoint, a keen knowledge of human nature—a faculty so necessary in the clever physician. The Anatomy, at the best a stumbling-block to students, is made more interesting by excellent illustrations, as are the numerous operations. The directions for treatment are sane but conservative and up to date. Aside from its medical excellence, the book is published in a size convenient for use by students.

The Practice of Obstetrics. Designed for the Use of Students and Practitioners of Medicine. By J. Clifton Edgar, Professor of Obstetrics and Clinical Midwifery in the Cornell Medical College; Visiting Obstetrician to Bellevue Hospital, New York City; Surgeon to the Manhattan Maternity and Dispensary; Consulting Obstetrician to the New York Maternity and Jewish Hospitals. Fourth Edition, Revised, Twenty-second Thousand, with 1316 illustrations, including five colored plates and 36 figures, printed in colors. Price $6.00 net. Philadelphia: P. Blakiston's Son & Co., 1913.

In this revision of the fourth edition of this work the entire text has been carefully reviewed and in some parts rewritten, as that on the pathology of the various subjects. The work is divided into ten parts and arranged under subheadings, so that one subject leads naturally to a more advanced and complicated one. Much new material has been added without appreciably increasing the size of the volume. In the chapters on the Physiology and Pathology of Pregnancy, the new notes on blood-pressure are clear but concise. So much has been promised and so much expected of vaccine therapy in the other branches of medicine that it is interesting to learn the author's attitude toward this treatment in the field of Obstetrics. He has used it persistently and over a length of time in the treatment of puerperal infection, but without success. A polyvalent serum, on the other hand, has given marked results. The volume abounds in good illustrations, which in themselves should be of great help and instruction to physicians and students who have not easy access to maternity hospitals and clinics. As a book for study and reference, it admirably fulfills its purpose.

A Laboratory Handbook for Dietetics. By Mary Swartz Rose, Ph.D. Assistant Professor, Department of Nutrition, Teachers' College, Columbia University. Price $1.10. New York: The Macmillan Company, 1912.

Although primarily designed to facilitate the work of the teacher and student in the Dietetic Laboratory, this little manual of 127 pages will also find a useful place in the armamentarium of the general practitioner. It does not aim to be a treatise upon the subject of nutrition, but it puts in easily accessible form the explanations involved in the calculation of food values and food requirements, and a consultation of its twenty-one reference tables will minimize the labor involved in the construction of dietaries without limiting dietary study to a few food materials. Thus, beside being a handbook for the student, it also serves as a guide to the physician and nurse in the practical preparation of the particular diet which is theoretically indicated. An admirable index enhances the value of the work.

Essai sur le Traitement des Cystites par l'Enfumage Iode. Par le Docteur Gaston Farnarier, de la Faculté de Médicine de Paris; ancien externe des Hopitaux de Marseille et de la Clinique des Maladies des Voies Urinaires, etc. Paris: Imprimerie de la Semaine Médicale, 1912.

The author gives a review of his predecessors' experiences with iodine in the genitourinary tract, the salient chemical features of the element, his technique of injecting the fumes into the urinary bladder, and the details of nineteen cystites thus treated. His technique of the procedure is quite simple. The iodine is generated in vapor form by heating iodoform in a glass flask and then injected through a catheter by means of Guyon syringe. Six acute cystites were cured in from four to twelve treatments, eight chronics were improved, three gave no result and two cases were exaggerated.

Diseases of the Skin. By Willmott Evans, M.D., B.S., B. Sc., F.R.C.S. Surgeon to the Royal Free Hospital, and Surgeon to the Skin Department, Royal Free Hospital; Senior Surgeon to the Hospital for Diseases of the Skin, Blackfriars. Thirty-two illustrations. Price $3.75. London: University of London Press, Hodder & Stoughton and Henry Frowde, 1913.

The author states that this book is intended as an introduction to the study of the diseases of the skin. The subject matter follows the usual order employed in such works, and it is written in such a simple, clear manner that it should prove a valuable aid to practitioners of dermatology, but especially to students. The chapter on eczema is unusually interesting, since the author has so grouped the various types of the disease that comparison is made without difficulty, and thus aids in the study of the subject. The illustrations are abundant, many of them being original, and add greatly to the value and interest of the work. The book is attractively bound, the print clear and the arrangement of paragraph and heading makes it convenient for reference.

Genitourinary Diseases and Syphilis. By Henry H. Morton, M.D.; Clinical Professor of Genitourinary Diseases in the Long Island College Hospital; Genitourinary Surgeon to the Long Island and Kings County Hospitals and the Polhemus Memorial Clinic; Consulting Genitourinary Surgeon to the Kings Park State Hospital and the Beth Israel Hospital of Newark; Member of the American Association of Genitourinary Surgeons; Member of the American Urological Association; Fellow of the New York Academy of Medicine. Illustrated with 275 half-tones and photoengravings and 18 full-page insert plates, 11 of which are in colors. Third edition, revised and enlarged. Price $6.00 net. Philadelphia: F. A. Davis Company, 1912.

The present edition of this work has been brought up to date by introduction of the essentials of recent syphilis therapy, the later advances in the technique of prostatectomy, the determination of the kidney function, pyelography, and the treatment of vesical neoplasms by the Oudin current. The author has the rare good judgment to select and ability to present in concise, readable form the vital parts of his subject, which should be included in the foundation of every general practitioner's education. Despite its general excellence, however, such a debatable statement as "gonorrhea is a *self-limited* disease——" cannot pass unchallenged, since its acceptance by an undiscerning reader might readily bring about calamitous results.

Food in Health and Disease. By Nathan S. Davis, Jr., A.M., M.D., Professor of the Principles and Practice of Medicine in Northwestern University Medical School; Physician to St. Luke's Hospital, Mercy Hospital and Westley Hospital, Chicago; Member American Medical Association, American Climatological Society, etc. Second edition. Price $3.50. Philadelphia: P. Blakiston's Son & Co., 1912.

The first edition of this work formed a volume in the series of Physiologic Therapeutics, edited by S. S. Cohen. In its present form it is much enlarged, has been thoroughly revised, and should receive a much wider recognition. The book is divided into two parts. The first part is devoted to general principles and diet in health, with chapters on: Food in Health, Uses of Water, Elements of Food, Quantity and Kind of Food Needed in Health, Animal Foods, Vegetable Foods, Beverages, Diet in Health, Infant Feeding, and Food as a Cause of Disease. The second part is on Diet in Disease, with chapters on Feeding the Sick, Diet in Infectious Diseases; in diseases of the stomach, intestines, liver, peritoneum, the respiratory organs, of the blood, of the circulatory system, of the kidneys, of the nervous system, of the skin, and in disorders of nutrition. The author calls special attention to the numerous studies of food and dietetics prosecuted under the auspices of the United States Department of Agriculture, and under the supervision of Professor Atwater. The volume is of much value, and should stimulate interest in a branch of therapeutics which has been greatly neglected.

# Society Reports.

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON SURGERY.

*Stated Meeting, Held February 7, 1913.*

DR. LUCIUS W. HOTCHKISS IN THE CHAIR.

**Ureterocele; Occlusion of Ureter and Hydronephrosis.**—Dr. LEO BUERGER presented drawings and *x*-ray plates illustrating the case of a man who entered the genito-urinary service of Mt. Sinai Hospital because of lumbar pain and pain radiating down the left lower extremity. He had been admitted to the genitourinary service because of pyuria that had persisted for almost a year. Cystoscopic examination revealed a remarkable picture. Occupying the site of the left ureter, there was a pyriform cystic mass about the size of the terminal phalanx of a middle finger, its base occupying the situation of the left ureter. At the summit, one could, with some difficulty, discern a flat slit-like opening that represented the occluded or compressed ureteral orifice. At a subsequent cystoscopic examination with the author's operating cystoscope and endoscopic knives, several incisions were made into this tumor mass, and finally the swelling was made to collapse. The ureter could then be plainly seen, lying in the center of redundant swollen mucous membrance. The telescope of the cystoscope was removed in order to introduce a catheter into this ureter, and, upon reinsertion of the telescope, the cystic mass was seen to have filled up again. It therefore was apparent that a simple incision would not suffice as a curative measure, and a large hole was punched into the cyst wall by means of the author's cystoscopic forceps. At a subsequent examination, two catheters were easily inserted into this ureter, argyrol was injected, and an enormous hydronephrosis was demonstrated by the *x*-ray plates.

Dr. FRANZ J. A. TOREK reported a case of ureterocele. He thought at first that he was dealing with the vas deferens and discovered that he was dealing with the ureter only after considerable dissecting.

**A Case of Imperforate Anus with Vaginal Outlet of the Rectum.**—Dr. LEO BUERGER presented a child sixteen months of age, on whom, three months previously, he had performed a plastic operation for imperforate anus, there being a small orifice in the posterior wall of the vagina near the posterior fornix. The child had been constipated ever since birth, because of the small size of the abnormal anal outlet. By means of a plastic operation, the rectum was freed from the posterior vaginal wall and implanted in the region of the dimple marking the normal situation of an anus. In presenting this case, in which the operative results were satisfactory, Dr. Buerger wished to point out the following facts: First, that in cases where the abnormal outlet was very small, the ampulla of the rectum became enormously dilated, indicating chronic coprostasis. It was for this reason that it would seem proper to operate upon children early because dilatation of the colon must undoubtedly occur if the chronic intestinal obstruction was allowed to persist for too long a time. Second, in treating such cases after operation, it did not seem wise to constipate the children as was proper in adults because stasis occurred, and the line of suture was stretched and torn by the expulsive effort of the child. Third, there was a tendency toward cicatricial contraction around the new formed anus which must be treated by dilatation, until such time when a plastic operation in the formation of a new sphincter arose.

Dr. FRANK C. YEOMANS said there was no sphincteric control because there were no muscular fibers present. With regard to the time for operation, none should be attempted until after the first year, when the patient could stand an operation. In those under this age there was danger from the loss of blood. Sphincteric fibers could be obtained from the gluteal muscles, dissecting the fibers out and bringing them down around the anus in a figure-of-eight fashion.

Dr. CHARLES R. L. PUTNAM reported an operation which he had performed upon a child seven years old. The coccygeus muscle was brought down into the median line where he had brought the anus out and fastened it. The result was that when the child wished to control his movements he drew in his coccyx; this was a bony action comparable to what was noted in some animals. In this case the child had but one movement a day.

Dr. LEO BUERGER emphasized the importance of dilating well the lower end of the rectum. If the child was constipated, one could see the pouch that was formed by the accumulated feces. He did not see what good purpose was obtained in giving these children some agent which would bind up the bowels for any length of time. Let them have their movements right along.

**A Case of Tuberculosis of the Kidney Diagnosticated by the Author's New Method.**—Dr. LEO BUERGER showed a case of tuberculosis of the kidney in which he had performed a nephrectomy, diagnosis having been in doubt because of the absence of tubercle bacilli in the urine, the absence of conclusive changes in the bladder mucosa, and the inability to obtain specimens from the affected side. By means of a new method, namely, the removal of pieces of edematous mucous membrane from the suspected ureteral orifice with consequent microscopic examination of the sections, a positive diagnosis of renal tuberculosis was made which was afterwards confirmed by the nephrectomy.

Dr. JOSEPH F. MCCARTHY said he had had experience with a similar forceps which he had used a great deal. He recently saw Dr. Squier do a resection of a growth in the vault of the bladder which had existed for about two months. There was much corrugation. The growth afterwards proved to be carcinomatous.

Dr. BENJAMIN S. BARRINGER said he was much interested in the method of diagnosing tuberculosis as described by Dr. Buerger, but it seemed to him that this was an extraordinary way for him to show his skill in the use of the cystoscope rather than a method of diagnosis of renal tuberculosis. The use of tuberculin would have settled the question, and should be used in cases of this sort.

Dr. HENRY DAWSON FURNISS believed that what Dr. Buerger had stated about these renal tuberculosis cases was correct and especially where there were other changes about the orifice of the ureter. There was one change in tuberculosis of the ureter which was nearly always present, a retraction into the bladder. He had now one patient under observation with this retraction and induration which could be readily felt. The urine was clear. There was frequency in urination and renal pain on one side. The radiograph showed that there were no cavities in the kidney. There was a marked reaction from tuberculin, but no tubercle bacilli could be found by any method employed; the injection of guinea pigs gave negative results.

Dr. LEO BUERGER said he was certain that the urine was coming down from the kidney, but the tubercle bacilli would not come down in sufficient number to enable him to make a diagnosis from an examination of the urine. They probably were there, but he could not detect them. He believed that in every case where there was edema miliary tubercles would be present. By removing a piece of the tissue as advocated one would be able to make an earlier diagnosis which was so important.

**Case of Arthroplasty (Murphy) for Ankylosis of the Knee.**—Dr. EDWIN BEER presented a woman who had had an old ankylosis of the knee joint. He was not at all enthusiastic over the operation, the typical Murphy one, nor over the results obtained in this instance. It was seven months since the operation and the results he did not consider at all brilliant. An interesting thing was that the joint between the patella and the femur was free, while in the one between the tibia and the femur, although freed of adhesions three times, they invariably recurred. Everything possible had been done for this patient, such as the employment of massage, hot air, Bier's hyperemia treatment, et cetera, with the result that the motion was increased but a few degrees. In looking over the report of Murphy's cases he had been very much surprised at his conclusions.

Dr. LUCIUS W. HOTCHKISS said that his experience with this operation had been very limited. He recalled one case of ankylosis of the elbow joint where the results from operation were not at all brilliant. He had his suspicion that the results obtained were caused by the extremely bad method employed. One could not, in his opinion, predicate just what the outcome was going to be.

**Traumatic Cyst of the Pancreas.**—Dr. CHARLES GOODMAN reported the case of a girl, fourteen years of age, who, nine weeks previous to admission to the hospital, had fallen from some rocks and struck on her abdomen. She was immediately taken to Fordham Hospital and an abdominal operation was performed. At the end of eight weeks she was sent home. Three days later she was seized with violent abdominal pain, rise of temperature, profuse and persistent vomiting which was not relieved at the end of two days, and she was, therefore, taken again to the hospital. She was a thin and emaciated girl. In the upper abdomen she presented an arching of the abdominal wall covering a smooth globular mass,

somewhat tympanitic on percussion; there was no rigidity. The pulse was 124, the temperature 95.5°. The leucocyte count was 10,000; the red blood cells 2,200,000. The examination of the urine was negative. The Cammidge reaction was negative. Upon opening the abdomen the stomach and greater omentum were found firmly adherent to the abdominal wall. After separating some of the adhesions they discovered a very large cystic tumor; in order to determine the point of selection of aspirating the tumor, they passed the stomach tube and found the stomach empty, contracted, and pushed up against the anterior wall where it was firmly adherent. Having outlined the greater curvature of the stomach, the cyst was aspirated, a large quantity of turbid fluid was evacuated, and a large degenerated clot removed from the bottom of the sac. There were some spots on the omentum which appeared like patches of necrosis. The sac seemed to be firmly and intimately connected with the posterior wall of the stomach. It was impossible to remove the sac wall and drainage was therefore introduced and the wound sutured. All was progressing favorably for four weeks when the patient was again seized with an attack of her former symptoms, and a swelling again made its appearance in the upper abdomen. Dr. Lewisohn, who had charge of the case during Dr. Goodman's absence, again operated and evacuated a large quantity of fluid from a pocket in the region of the lesser omentum. She improved rapidly and was discharged three weeks later. Since that time she had remained quite well and had gained considerably in weight. The stools were normal. The case was really one of so-called pseudo-pancreatic cyst, traumatic in origin. The tumor fluid was clear with some tryptolytic ferment, but no liptolytic nor amylolytic ferments were present. The cytology was negative except for leucocytes.

Dr. Leo Buerger asked how much time had elapsed between the receipt of the injury and the time of operation. It seemed to him that it was only through the pathological findings that they could assume that any cyst was of traumatic nature. They might find evidences of old organized blood, or the presence of blood pigment, or other evidences that one usually got. It should be remembered that clots might form secondarily in the cysts. However, one should look askance on this, for there might have been a secondary hemorrhage in the cyst.

Dr. George Franklin Shiels believed that traumatic cysts in most organs were unusually common; injury certainly had a causative influence. He said he had had some experience with traumatic cysts of the pancreas.

Dr. Lucius W. Hotchkiss said the classification of cysts of the pancreas was far from being an accurate one. He had had some experience with these cases and he believed that cysts of the pancreas were very difficult to describe pathologically. The results of the Cammidge reaction were rather variable.

Dr. Charles Goodman said that the patient was operated upon eight weeks after the injury. The patient fell down a hill and struck on a rock. There was a large and partly organized clot of blood in the cyst which was so common in pancreatic or peripancreatic cysts. He used large gauze packings, drainage tubes, et cetera, and he thought of the possibility of some interference with the healing process because of the presence of ferments.

**Case of Pulmonary Emphysema; Its Surgical Treatment.**—Dr. Charles Goodman presented this case. As a result of studies begun fifty years ago Freund of Berlin contended that the abnormal arrest in the development and the consequent shortening of the costal cartilages of the first rib, combined with the resultant narrowing of the superior strait of the chest, were important anatomical predisposing factors in tuberculous infection of the apex of the lung. This led him to advance the theory that a correction of this condition in flat chested people was a rational procedure, as both a prophylactic measure and a potent curative measure in the incipient stage of this disease. His pathological findings had been confirmed by other investigators. Freund also contended that the generally accepted theory that the barrel-shaped chest, in certain forms of emphysema, was caused by the condition of the lungs was not true. He claimed that the reverse was true and constantly asserted that the rigidity of the chest, due to pathological changes in the ribs and costal cartilages, was the forerunner of the changes in the lungs, which were associated with the symptom complex, recognized clinically as pulmonary emphysema.

The patient was forty-eight years of age and was admitted to the Montefiore Home after having drifted from one institution to another in efforts to get relief from his symptoms. He claimed that six years ago, after contracting a severe cold, his cough persisted, his dyspnea gradually became more marked, and his expectoration profuse. He was only able to walk a block or two without being obliged to rest to regain his breath. Walking up a flight of stairs was followed by a violent fit of explosive coughing, so that he would expectorate all over his customers. It was this disagreeable complication that made him a veritable nuisance. Through the courtesy of Dr. Wachsman he had the case transferred to the Beth Israel Hospital where he operated before the Clinical Congress. He removed a segment of the second, third, fourth, fifth, and sixth cartilages of the right side. In order to prevent a regeneration of the cartilages and a recurrence of the rigidity of the ribs, he interposed both the anterior and posterior layers of the perichondrium over the resected ends. This procedure was described by Dr. Goodman in his presentation of cases before the Section on Medicine in 1908. Since the operation the patient's chest expansion had increased from ¾ to 1½ inches and his vital capacity proportionately. His dyspnea was decidedly relieved and the cough and expectoration were very much diminished. His previously cyanotic appearance was now also absent. Of course the purpose of the operation was a purely mechanical one, viz., to correct the rigidity of the chest and give the remaining lung tissue an opportunity to functionate. It was important that these cases should be subjected to respiratory gymnastics in order to improve and restore the functional condition of the lungs as far as possible. The operation was indicated only in cases of emphysema with rigidity of the chest.

Dr. Lucius Hotchkiss asked Dr. Goodman if he had sufficient faith in the operation to recommend it in other than selected cases.

Dr. Charles Goodman replied that these patients took anesthesia very well. His first case he did under local anesthesia. He emphasized the importance of bringing over the cut surfaces the perichondrium to prevent the reformation of the cartilages. His second case was decidedly relieved by the operation in spite of the fact that the patient suffered so much from his asthmatic attacks that he took in four months seventy ounces of adrenalin chloride hypodermically to relieve him of his attacks. The first case was decidedly relieved in spite of the fact that he had all the complications that could be enumerated in emphysema.

**A New Method of Diagnosticating Renal Tuberculosis.**—Dr. Leo Buerger read a paper describing a new method of diagnosticating renal tuberculosis. Portions of the edematous mucous membrane about a suspected ureteral orifice were removed by means of a punch forceps through the author's cystoscope and submitted to pathological examination. The author's conclusions were the following: (1) It had been shown definitely that the excision of mucous membrane of the ureteric meatus might yield tissue containing miliary tubercles, at a time when no positive evidences of tuberculosis of the kidney were at one's disposal. (2) Miliary tubercles might be present in such tissue, although the only visual alterations of the mucous membrane were those which appeared as "edema" even to the trained eye. (3) Such excised pieces made a positive diagnosis possible when the ureteral catheter failed, when the guinea-pig inoculations were negative, when the urine was perfectly clear, and when the patient was presenting practically no symptoms. (4) Concentration and focalization of the tuberculous process at a ureteric meatus might occur early in the disease. (5) Such miliary tubercles might be found in the ureteric ostium even though the rest of the ureter was almost free from tuberculous change and when the pelvis of the kidney, too, was but slightly affected. (6) Cystoscopic biopsy should be performed on the ureteric orifice of the affected side in all cases of suspected renal tuberculosis where the ocular evidences were sufficient to warrant a suspicion of renal involvement; also whenever tubercle bacilli could not be demonstrated, and whenever positive evidences of the presence of a tuberculous process in the kidney were lacking.

**The Use of Needles in Fractures and Epiphyseal Separations.**—Dr. C. L. R. Putnam described this method which was illustrated by one case of fracture of the neck of the radius and another of separation of the lower epiphysis of the humerus which had been fastened with needles.

**Experimental Ligation of the Portal Vein and Remarks on the Treatment of Suppurative Pylephlebitis.**—Dr. Harold Neuhof read this paper. He stated that this report was from the pathological laboratory of Prof. Ludwig Pick, Krankenhaus Friedichshain, Berlin, who supervised the work and placed all the laboratory facilities

at his disposal. The fact that there was no surgery of the portal vein as yet developed depended upon the results of animal experimentation. Many observers had demonstrated that ligation of the portal vein led to death in a very short time—in one-half to two hours. As a result of these experiments the human portal vein had been considered a *noli me tangere*. Although the portal vein had been more or less completely ligated for accidental injury in a very few instances, a deliberately planned ligation of the vein had never been practised. The author believed that of the diseases involving the portal vein, suppurative pylephlebitis was a condition for the treatment of which a knowledge of portal vein ligation was at present indicated. With this in view the present study was made. In order to determine if animals could live after any form of portal vein occlusion, it seemed desirable to ascertain the cause of death after complete occlusion. In several successive experiments, the portal vein was completely tied off and death followed in a short time and in a surprisingly uniform manner. Respiration became superficial and accelerated. Considerable abdominal distention developed. The pulse was generally slow and compressible. In those animals recovering consciousness no pronounced weakness of the lower extremities was noticeable. Death was ushered in by generalized convulsions. Post-mortem examination revealed moderate distention of the stomach and enormous distention of the small intestine. The latter was deeply cyanotic; the intestinal wall was intensely edematous and firm, and showed numerous larger and smaller submucous hemorrhages. The lumen contained some blood. The spleen was enlarged to two or three times its normal size and was plum-colored. The organ was very firm, its capsule tense, and there were extensive subcapsular hemorrhages. The remaining viscera were somewhat anemic but not blanched. The intense acute engorgement of the intestinal tract and the extreme intestinal distention had been found to be the cause of death both in human beings and in animal experimentation carried out for various purposes, and it was now generally held that death in such instances was due to shock. It was therefore logical to conclude that death from complete ligation of the portal vein was due to shock. The next question which arose was whether death was found to follow so promptly upon portal vein ligation when the ligations were made at different levels. It was first demonstrated by Solowieff that dogs could survive occlusion of the portal vein if the branches were ligated at different times. He ligated the superior mesenteric vein at the first operation; the gastrosplenic vein a few days later, and, finally, the portal vein above the gastrosplenic. Some of the animals thus operated upon lived weeks and even months after the operation. Dr. Neuhof repeated Solowieff's experiment and could confirm his results. After citing several of these experiments, he said that it was evident that the results of portal vein ligation hinged largely upon the establishment of a collateral circulation. Attempts had been made to establish a collateral circulation experimentally by means of omentopexy and then to ligate the portal vein at a subsequent operation and occasional successes by this procedure had been reported. The method employed for this purpose was not practical in human beings and hence the author determined to attempt complete ligation of the portal vein by several operations directed at the vein itself, to ascertain if dogs would live under such circumstances, and if a definite type of collateral circulation would regularly develop. The plan was to moderately narrow the lumen of the portal vein at the first operation; at the second operation several days later to place a ligature that would further encroach upon the lumen; and, finally, to completely ligate the lumen at the third or fourth operation, depending upon the behavior of the intestine when the vein was provisionally clamped off. This general plan was successfully carried out in several instances, the details of which Dr. Neuhof described. The experiment established the fact that complete occlusion of the main trunk of the portal vein was experimentally feasible provided such occlusion was gradually induced during a period of several days. An efficient collateral circulation developed chiefly in the gastrohepatic omentum. These experiments established two facts, namely, that the collateral circulation developed with great rapidity, and that the collateral circulation in the gastrohepatic omentum was the one that regularly developed. In regard to the significance of the findings together with clinical observations in respect to the treatment of suppurative pylephlebitis, Dr. Neuhof said that as it was difficult to foresee any other than a fatal outcome from this affection, any procedure, no matter how radical, that offered a possibility of cure should be advocated. He therefore suggested ligation of the portal vein. This procedure was especially to be recommended in those cases which were not rapidly fatal. Even involvement of the liver was not necessarily a contraindication. The details of the operation could be developed by experience alone. In cases of pylephlebitis, which had existed for some time and in which the collateral circulation had had an opportunity to develop, immediate ligation would be the operation of choice. Whatever the operation of occlusion practised upon the portal vein, it should be combined with an omentopexy. This additional procedure was advocated because it might prove a valuable aid to the collateral circulation that had already developed at the time of the operation.

**Specimens of Tuberculosis of the Kidney.**—Dr. Marcus I. Blank presente dtwo specimens of renal tuberculosis. In both cases there was a history of cystitis. The specimens were but a little larger than the normal kidney.

---

SECTION ON MEDICINE.

*Stated Meeting, Held February 18, 1913.*

Dr. Linsey R. Williams in the Chair.

**Artificial Pneumothorax: Its Indications and Contraindications.**—Dr. S. Adolphus Knopf read this paper. He defined artificial pneumothorax as an operation which consisted in filling the affected side of the tuberculous chest with sterilized atmospheric air or some gas, oxygen or nitrogen, for therapeutic purposes. Experience had shown that by collapsing and compressing the affected lung the production and absorption of toxines resulting from mixed infection were greatly diminished. When the affected lung was put at rest there was, concomitant with the diminution and total disappearance of the mixed infection, a constitutional improvement. The gas which had been found preferable for this purpose was nitrogen. Dr. Knopf said that his personal experience with this method was still limited, but what he had seen, heard, and done himself, together with the perusal of the literature at his disposal, enabled him to make the following statement concerning the indications for the production of artificial pneumothorax: 1. Artificial pneumothorax was indicated in all such cases as had not improved under ordinary hygienic, dietetic, climatic, and symptomatic treatment, such cases, as a rule, being moderately or far advanced. 2. It was indicated in these earlier cases in which there was no improvement because of mixed infection, or lack of recuperating powers, or when for inexplicable causes the condition remained stationary or the progress was particularly slow. 3. It was indicated in all rapidly progressing cases, whether treated in institutions or at home, and in no matter what climate. 4. It was indicated for all patients of the moderately or far advanced type who were discontented and felt that not enough was being done for them. 5. It was indicated in uncontrollable hemorrhage or chronic sanguine expectoration. Dr. Knopf stated emphatically that bilateral involvement, if one lung was considerably and the other one much less involved, was not a contraindication to the production of artificial pneumothorax. Where the disease had existed for any length of time it was seldom limited to one side. All the cases which he had seen operated upon or had operated upon himself had had bilateral lesions, and, so far as the immediate symptomatic improvement was concerned, everyone of them showed gratifying results. Casts and albuminuria were not necessarily a contraindication, but one must be guided by the general condition of the patient. Some authorities considered a basal lesion of the less affected side as a contraindication, but, in the opinion of Dr. Lapham, who had perhaps had a larger experience with this method than any other physician in the United States, this condition was not an absolute contraindication, and the production of artificial pneumothorax was permissible because of the relief which it gave the patient. The contraindications to the production of artificial pneumothorax were (1) an extensive involvement of both lungs, (2) so much cavitation that there was danger of the needle entering a cavity, (3) myocarditis, other serious cardiac complications, or serious renal complications, (4) any pulmonary tuberculosis complicated by a constitutional disease which in itself was sufficient to inhibit all possible chances of recovery, (5) when the patient was too apprehensive and strongly objected to the performance of the operation. That artificial pneumothorax was a valuable adjuvant in the treatment of pulmonary tuberculosis was now an established fact, yet in view of the possibility of an accident every practitioner should protect himself by pro-

curing the written consent of the patient, parent, or guardian, before resorting to this operation. There were various accidents which might occur, such as air, embolism, cardiac or pleuritic shock resulting in failure of respiration, spasm of the glottis, aphonia, and inability to cough. Hemorrhage or subsequent neuritis might also occur as the result of injury to a blood vessel or nerve. Pleurisy with effusion had been reported in a number of cases from artificial pneumothorax. Emphysema was also an occasional complication. Weiss had reported a case of fatal pneumonia in the other lung notwithstanding that the nitrogen was withdrawn. Dr. Knopf believed that the technique of the operation could be improved. He stated that up to a year ago he had been very skeptical about the immediate as well as the ulterior results of artificial pneumothorax, but what he had learned during the past months concerning this procedure had convinced him that artificial pneumothorax would often help when all other means had failed; however, he was not such an enthusiast as to consider it a cure all. He felt that gratitude was due the pioneers in this field for having given them a means of lessening the sufferings of tuberculous invalids, rendering them comfortable and free from many of the distressing symptoms, and in not a few instances bringing about an arrest of the disease.

**Artificial Pneumothorax: Its Technique and Results**—Dr. Mary E. Lapham of Highlands, N. C., read this paper. She stated that when a tuberculous lung was well compressed by filling the pleural cavity with nitrogen the distention of the cavity was shown by the bulging of the ribs, by the rotary breathing as if the other half of the thorax moved around a fixed point, and by the deep hollow resonance which often extended well over on the other side. This empty space was obtained at the expense of the lung which was driven up into the smallest bulk possible and held there like a dried sponge, immobile and incapable of expansion. As the lung became smaller and smaller the râles disappeared and the breath sounds became suppressed or assumed a metallic character finally changing to the sound of a drop falling into a metallic space or to a sharp metallic clink. To all intents and purposes the lung was not there, and while it was held firmly compressed connective tissue infiltration converted the tuberculous lesion into clean healthy scars. In such a recovery there was nothing to cause a relapse. There were no tubercle bacilli threatening resumption of activities. It seemed unlikely that any portion of the lung that had been destroyed could be replaced, and yet after reexpansion normal resonance and breath sounds appeared in lungs in which before compression nothing but râles and altered breath sounds could be heard. It seemed to be proven beyond question that compression of the lung did not injure the normal portions and that the diseased portions were singularly benefited. The clinical results were no less marked than the physical signs. As the pressure of the nitrogen crowded the lung upward, the decomposing masses were forced out through the mouth so that at first there might be pain, higher temperature, increased coughing, and expectoration. After about a year it was safe to allow the lung to expand and to resume its functions. Balboni said, "It is absolutely essential for the success of the treatment that the pneumothorax be maintained of such a volume and tension so as to squeeze out and practically dry the lung of all secretions." The maintenance of this volume and tension was the keynote to success and was therefore the main point of technique discussed in this paper. If dulness and altered breath sounds persisted over any part of the lung adhesions were preventing its compression. In using pressure to break up these adhesions the sudden application of too much force was to be avoided. Many cases reported as failures because of empyema, or pulmonary fistulæ, or tension pneumothorax, might be explained in this way. Later on the condition of the other lung might forbid too much nitrogen in the pleural cavity. Too much intrathoracic pressure impeded the return circulation and threatened stasis of the gastric intestinal circulation which might cause insomnia, anorexia, cardiac distress, neurasthenia, hysteria, and a host of other troubles. The other lung might become so congested as to cause wet râles and frothy sputum and this edematous infiltration must be relieved by reducing the intrathoracic pressure or broncho-pneumonia might result. The other lung needed constant examinations to detect the first signs of an edematous infiltration. Chilling and too much exercise must be carefully avoided until it is certain that the other lung was not concealing a hidden, deep lesion, or peribronchitic infiltration which did not manifest itself by physical signs until too late. If insufficient pressure to produce a breaking up of the adhesions around a cavity was applied our efforts were lost and nothing was accomplished. To keep up enough pressure to extend the resonance without injuring the patient was the problem. In these cases they had found the daily estimate of what was needed and the daily injection of enough nitrogen to meet these needs was the most satisfactory way of overcoming the difficulties. As the nitrogen was absorbed and the dulness returned, it was replaced by the resonance of nitrogen and in this way they had succeeded with infinite patience and time in compressing the lung and breaking up adhesions that seemed invincible. A fine hypodermoclysis needle was preferable to a large needle in these cases. In severe bilateral cases with great general exhaustion and poor condition of the heart and other lung, the use of oxygen had been found of great benefit. When nitrogen caused dyspnea and cardiac distress, oxygen might give the same relief that an intubation tube did to a child struggling for breath. After the insertion of the tube the use of oxygen promised to extend the usefulness of the method to cases too difficult for nitrogen because it had a tonic strengthening influence instead of the depressing one of nitrogen. As Dr. Knopf had said most of the accidents had occurred after the first injection of nitrogen and for this reason they had been laboring during the past few months toward bringing about a safe method for a permanent opening into the pleural cavity and had sought the best surgical council that they could obtain. With Dr. Thomas A. Smith's guidance and cooperation in New York and their continued experimentation in Highlands, Dr. Knopf and Dr. Lapham hoped soon to be able to report progress.

Dr. Samuel Lloyd said that during the past fifteen or eighteen years he had been experimenting in lung surgery and he was glad to hear that men on the medical side were willing to accept operative surgery in unilateral lung disease. They had met with many difficulties in lung surgery, for many years believing that the pleural cavity could not be entered except in the presence of positive pressure apparatus. Dr. Lloyd said that during the past fifteen or eighteen years he had been experimenting with cases in which a single lung was involved, trying the possibility of opening the pleural cavity without any pressure apparatus, or apparatus of any kind. The lung was approachable and could be treated without any special apparatus; the cavities could be opened and applications made from the outside. The sooner they recognized this possibility, the better. Dr. Meyer's warning regarding the possibility of cerebral embolism occurring in these operations scared many off. Six years ago a patient on whom they had produced an artificial pneumothorax became so distressed that they did not believe he would be able to get off the table. The keystone of the arch in the treatment of these cases was the use of the manometer. No distinction had been made between left and right-sided tuberculosis. Relatively speaking the heart was endangered when the tuberculosis was on the left side because of a dislocation of that organ and a twisting of the basic vessels. One should make a distinction between the two sides and be more cautious when operating on the left than on the right side. When nitrogen was introduced into the human chest at 70° F. it soon became 98°, 99°, or 100°, and in febrile cases 102° or 103°. If one injected 900 c.c. of the gas at 70°, the temperature soon rose to 100°, a difference of 30°. If one read the figures of the Robinson apparatus and with the employment of the Floyd needle, 900 c.c. of nitrogen gas introduced into the chest at 70° soon rose to 100° in the chest cavity. Dr. Lloyd thought that it was a wise precaution in all cases, especially in the young, to obtain a written consent for the operation. It should never be performed on a minor without such a consent, which would protect one if a case was brought to a court of law.

Dr. Mary E. Lapham believed that the right sided cases of tuberculosis gave more trouble than the left sided cases because of the liver disturbances which might follow.

The following were contributions from the medical wards of the Post-Graduate Hospital.

**An Intensive Study of the Prevalence and Distribution of Pellagra.**—Dr. J. F. Siler and Dr. P. E. Garrison presented this communication which was read by Dr. Garrison. Pellagra was a general disease characterized by the appearance of symmetrical lesions of the skin, usually occurring first of all on the dorsal surfaces of the hands and often confined to those surfaces. This characteristic manifestation was often preceded by more or less indefinite gastrointestinal disturbances and was nearly always accompanied by more or less severe stomatitis and enteritis with salivation and diarrhea. The immediate attack might result in death, but recovery from it was the rule, with recurrence the following year. It was largely a warm

weather disease and usually disappeared in the winter. Repeated annual attacks led to physical and mental deterioration, and as a result any latent tendency to insanity was likely to develop into serious mental disorder necessitating institutional care. Pellagra was very largely, but not exclusively, a disease of the poorly nourished. The disease was now widely prevalent in the southern United States, and a number of cases had been recognized in Pennsylvania, Rhode Island, and Illinois, the majority among the inmates of State charitable institutions. Last spring the New York Post-Graduate Medical School appointed a commission, financed by Colonel Thompson of New York and Mr. McFadden of Philadelphia, to study pellagra as it existed in the Southern States. The problem immediately before the commission in all its work was the etiology of pellagra and not its symptomatology or therapeutics, except as these subjects might throw light upon the essential nature of the disease. Accepting 280 as the minimum number of cases they had in Spartanburg County, S. C., in 1912, a minimum morbidity rate for the population as a whole of 0.35 per cent. or 35 cases of pellagra for each 10,000 of the population. Figures were presented which seemed to indicate that while congestion of population might play a part in the prevalence of the disease, it alone did not explain the marked inequality of distribution between the mill villages and the strictly rural communities. There was a strikingly excessive prevalence in cotton mill villages, and a tendency to greater prevalence in the more densely populated rural districts. The prevalence in the purely urban population about equalled that of the highest prevalence in rural districts. In Spartanburg County there were 257 cases of pellagra among 57,055 whites, or at the rate of 45 per 10,000, and 25 cases among 26,410 negroes, or at the rate of 9.5 per 10,000. In other words, while whites were present in the population in the proportion of two whites to one negro, there were ten white pellagrins to one negro pellagrin. However, the mill-village population, which appeared to show a marked excess of pellagra, was almost exclusively white. Comparing the white population outside of the mill villages and the negro population, the rates of prevalence per 10,000 for whites and negroes were 25 and 9.5. In other words, the disease appeared to be almost three times as prevalent among whites as among negroes living under similar conditions. Pellagra appeared three times more frequently among females than among males. There was a strikingly excessive rate among females between the ages of twenty and forty-five. One hundred and forty-two, or 64 per cent., gave housework as their principal occupation. It was evident that while pellagra was nine times more prevalent among the mill village population than among the rural population, this excess did not appear among the mill operators but among the adult women of the mills who were engaged in home duties about the house. Those theories of the causation based upon the idea of a metabolic disturbance due to a peculiarity of diet, such as the excessive use of maize or of cottonseed oil products or the use of spoiled maize, would seem to be inadequate to explain the excessive prevalence in certain geographical divisions or in certain groups of population. In their opinion, these inequalities in the distribution of pellagra in Spartanburg County were at least suggestive of the possible infectious nature of the disease and of its communicability.

**Metabolism in Pellagra.**—Dr. V. C. Myers and Dr. M. S. Fine presented this paper and offered the following summary: The ability of individuals suffering from pellagra to utilize the various food stuffs, as indicated by their series of experiments, appeared to be only slightly, if at all, below the normal. The elimination of mineral and nitrogenous constituents in the urine was such as would be anticipated under the dietary and physical conditions of the individuals. A lowered efficiency was indicated by the low creatinine coefficients and the elimination of small amounts of creatine in the urine. The presence of a few hyaline casts in about 45 per cent. of the cases pointed to some possible irritation of the kidney. Anacidity was a condition common to pellagra and was found in eight of their fourteen cases. It was generally associated with an entire absence of pepsin, or with pepsin in only very minute quantities. Individuals suffering from pellagra showed a marked indicanuria, which was excessive in the cases with gastric inefficiency. Though the ethereal sulphate hardly paralleled the indoxyl-potassium sulphate, the quantities eliminated were much higher where anacidity existed and they furthermore held a higher ratio to the inorganic sulphates. The feces contained decidedly abnormal amounts of indole and skatole, especially the latter. The presence of excessive amounts of indican in the urine, associated with a high elimination of ethereal sulphates, when considered in connection with the abnormal amounts of indole and skatole in the feces, pointed to some unusual bacterial conditions in the intestine. From the data at hand this putrefaction appeared to take place rather high up in the intestine.

**Some Observations on the Intestinal Bacteria in Pellagra.**—Dr. W. J. MacNeal read this paper. He said that a general survey of the fecal bacteria in pellagra was undertaken in 1910 and 1911 by the Illinois State Pellagra Commission. A brief summary of this work was published in the August number of the *Archives of Internal Medicine*, and the detailed record of the work had recently appeared in the report of the Illinois State Pellagra Commission, issued by the Illinois State Printer. Further study along similar lines had been undertaken by the Thompson-McFadden Commission at the New York Post-Graduate Medical School this past summer. The opportunity was here presented to test this culture against the sera of pellagrins in a different part of the country, South Carolina. These recent cases had been divided into four series: first, 66 pellagrins showing lesions on the skin at the time the blood was taken; second, 43 pellagrins who did not show an eruption at the time; third, 22 individuals living in the pellagrous district, Spartanburg County, S. C., but free from any sign or definite history of the disease; fourth, 27 individuals in New York. The agglutination tests were performed by the macroscopical method, a suspension of the bacteria in salt solution being mixed with an equal volume of a 20 per cent. solution of the serum in a small tube for each test, the final dilution of the serum being one in ten. It was incubated for an hour and the progress of events were recorded at intervals of fifteen minutes. Complete clumping and precipitation of the bacteria to the bottom of the tube was recorded as a complete reaction. Grades of almost complete, marked, slight, and negative were also distinguished. In the first series 51 gave complete agglutination, 5 almost complete, 3 marked, 3 slight, and 4 negative. In the second series 30 gave complete agglutination, 6 almost complete, 0 marked, 0 slight, and 7 negative. Of the whole 109 sera from pellagrins, 74.3 per cent. gave complete agglutination, 10.1 per cent. almost complete, 2.7 per cent. marked, 2.8 per cent. slight, and 10.1 per cent. negative reactions. In the third series 5 gave complete agglutination, 1 almost complete, 3 marked, 6 slight, and 7 negative reactions. In the fourth series 6 gave complete agglutination, 3 almost complete, 10 marked, 1 slight, and 7 negative reactions. Of the total 49 controls, 22.5 per cent. gave complete agglutination, 8.2 per cent. almost complete, 26.5 per cent. marked, 14.3 per cent. slight, and 28.5 per cent. negative results. These results were obviously not sufficiently clear-cut to warrant the assumption of a specific agglutination reaction of this bacterium with the serum of pellagrins, and yet they were such as to stimulate further work. The conservatism of this statement was not due to the fact that they had employed dilutions of 1 to 10 instead of higher dilutions of the serum, for many of these positive sera had been tested in higher dilutions, up to 1 in 400, and had produced very definite agglutination in such strength. The question of specificity was, however, seriously opposed by the fact that sera from normal individuals gave precisely parallel results in some instances. The work was in a very unfinished condition and no important conclusions could be drawn from it. It was presented to give an idea of one of the avenues along which they had approached the possible bacteriological phase of the problem of pellagra.

**A Case of Splenomegaly.**—Dr. O. S. Hillman reported this case. The diagnosis was made largely from a pathological point of view and by the process of exclusion. The spleen was somewhat enlarged and there were a large number of nucleated red cells. There was no cyanosis present. In the light of their present knowledge Dr. Hillman did not see what other diagnosis could be made. The leucocytes were largely increased in number as well as the number of myelocytes, the latter being as high as two per cent. There were a considerable number of mononuclears, or cells of the bone type, probably of the myeloplastic order.

Dr. Nathan E. Brill said that he recognized in the "case of splenomegaly" just reported by Dr. Hillman an old acquaintance. In fact the subject of this report was presented by him in life at the meeting of this very section in January, 1911, and reported subsequently by him in the Medical Record as "A Case of Erythemia with Unusual Features" in April, 1911. The patient had been under his observation at Mount Sinai Hospital for many months and was regarded by him as a classical instance of Vaquez's or Osler's Disease. While in England and

America the profession was wont to call the cases of polycythemia with enlarged spleen Osler's Disease, the honor of having described the first case belonged to Vaquez, who, in 1892, described in a patient, in whom he thought a cardiac lesion existed, a special variety of cyanosis and persistent polycythemia. Vaquez, three years later at autopsy, found the patient had a very large spleen but no cardiac lesion. This was the first case in literature, after which appeared, in 1899, cases described by Frenchmen, Rendu and Widal, Martin and Lefas; then by our countryman Cabot in 1899 and another in 1900. The clinical entity of the disease was afterwards hinted at by the Englishman, Dr. Russell, in Saundby's case. However, to Osler belonged the credit of having grouped the cases into a clinical entity, in 1904, by establishing the persistence in all cases of distinctive symptoms. Cyanosis, which, according to Dr. Hillman, was absent in this case, was not a necessary or essential factor of the disease. He would find in the literature many undoubted cases in which cyanosis did not exist. While this patient was under Dr. Brill's observation there was pallor though the tongue and palms of the hand were extremely red. The unusual features in this case, which he reported and which Dr. Hillman also found, were the marked hyperleucocytosis, 45,000 white blood cells, with definite myelocytosis (8 per cent.), showing a concomitant disturbance in the erythroblastic and leucoblastic activities of the bone marrow. A definite bone tenderness was also present as an exceptional feature. In fact, hyperleucocytosis had been reported by others, but a myelocytosis of eight per cent., which this patient showed, was extremely rare and with the other clinical feature of enlarged spleen, pallor, and bone tenderness might suggest the possibility of a leukemia. The erythrocytosis existing in this case absolutely excluded the possibility of a leukemia which was associated with a diminished and not with an excessive number of red blood cells.

**Contribution to the Bacteriology of the Duodenum.**—Dr. W. J. MacNeal and Dr. A. F. Chase presented this paper.

Dr. Anthony Bassler said that he had come to the conclusion that the bacteria found in the duodenum at autopsy were rarely of the pyogenic or putrefactive type of organisms. Dr. Herter believed that the duodenum probably became infected under certain conditions of the stomach and he believed, too, that the upper two-thirds of the small intestine was essentially sterile, so far as the important anaerobic bacteria were concerned. Recently Dr. Bassler had been making some observations of the duodenal contents and it occurred to him in a general way that when there was any delay in the exit of the stomach contents, with insufficient gastric secretion, this stagnation in the stomach permitted fermentation and putrefaction from bacteria, which bacteria passed on into the duodenum where they could also be found.

**Report of a Case of Digitalis Poisoning with Electrocardiograms Showing Heart Block, Fibrillation of the Auricle, Coupled Rhythm and Development of a Right Ventricular Hypertrophy.**—Dr. Robert H. Halsey made this report. The interesting features of this report were shown by the electrocardiograms, showing heart-block, auricular fibrillation, coupled rhythm, and the development of an hypertrophy of the right ventricle. He believed that a great deal was to be gained from a careful study of these electrocardiograms, and this study was along the line of work that had been done by Dr. Thatcher. In those cases with edema where digitalis was given without any prompt response by an increased output of the urine and a disappearance of the edema, one should be very cautious about pushing the doses of digitalis, or in keeping up large doses for any length of time. All these cases did not have nausea and vomiting as a preliminary symptom of digitalis poisoning; therefore, one should be very careful not to damage the heart by the too free use of this drug.

Dr. T. Stuart Hart said, in reference to hypertrophy of the heart, that ordinarily this developed very slowly, and that he had studied a series of cases (early valvular disease, early nephritis, etc.) in which hypertrophy might be expected to develop; repeated electrocardiographic records often showed only insignificant changes even after a period of six months. Another class of cases that Dr. Hart had studied were those in which the heart had been *displaced* by a hydro, or pneumothorax. After a *short time* when the fluid or air was removed, with a change in the position of the heart, there was a change in the electrocardiogram comparable to the changes in Dr. Halsey's records. It had also occurred to him that Dr. Halsey might have had an acute dilatation of the right heart with which to deal. He did not know whether this condition had been studied with the aid of the electrocardiograph; this was merely a suggestion. Dr. Halsey brought out a very important point regarding the effect of digitalis in increasing the irritability of the heart. In cases of auricular fibrillation everybody wanted to know what was the cause of the fibrillation. Patients with mitral disease with regularly acting hearts often had dilated auricles. In such a weakened cardiac musculature, might not digitalis increase the muscular irritability and thus be an efficient cause in inducing fibrillation? Cases had been reported in which the administration of digitalis had been followed by auricular fibrillation. Might not the digitalis be a very important factor in developing fibrillation?

**Galactose Test.**—Dr. Berton Lattin presented this communication in which, after reviewing briefly the galactose test of hepatic function, he gave the results of this test in their hands. They had used it on 58 patients 63 times. The results of 40 of these tests seemed worth while reporting and included all the cases in which liver disease could reasonably be excluded and all the cases in which an unequivocal diagnosis could be made. The following technique was employed: Forty grams of chemically pure galactose were dissolved in 500 c.c. of tea and given on a fasting stomach at the breakfast hour. The urine of the patient was collected just before the test and every hour up to four hours after the test. The specimens were examined qualitatively by the Fehling test and quantitatively by the polariscope. Following the arbitrary division of Reiss and Jehn, values under two grams for the four hours were considered slight galactosuria; two to four grams, moderate, and over four grams indicated pathologically diseased tolerance. The results of the investigation were summarized as follows: 1. Of 19 cases with livers clinically normal, 89.5 per cent. showed normal tolerance for galactose, 10.5 per cent. showing moderately alimentary galactosuria. 2. Of seven cases of hepatic cirrhosis, 29 per cent. showed moderately decreased tolerance for galactose, 71 per cent. showing normal tolerance. 3. Of eight cases of chronic passive congestion of the liver, all showed normal tolerance. 4. Of three cases of catarrhal jaundice two showed marked alimentary galactosuria, the third showing normal tolerance. 5. A single case of long standing jaundice, with solitary stone impacted in the common duct, showed normal tolerance.

**Visualization of Some Obscure Lesions of the Gastro-intestinal Tract by Means of the Röntgen Ray.**—Dr. Arthur F. Holding presented some radiographs showing among others the following: (1) Normal esophagus; (2) cardiopasm; (3) carcinoma of the stomach which involved the esophagus, producing as well a dilatation of the latter; at operation the lesion was found to involve the lesser curvature of the stomach; (4) ulcer of the stomach with an hour-glass contraction; (5) another case of ulcer of the stomach with hour-glass contraction (in both cases the clean cut indentation showed the process to be benign); (6) perforative ulcer of the stomach; the opening led into the lesser peritoneal cavity. He believed that much knowledge was to be gained by means of the fluoroscope which might be lost radiographically. In the paper he intended to read he brought out the fact that the sense of sight was better for diagnostic purposes than the sense of touch and lesions could often be visualized by this method more accurately than they could be felt at the operating table. (7) Carcinoma of the pancreas pressing upon the stomach; this occurred in a young child. (8) Metastasis from a teratomatous testicle pressing on the stomach posteriorly and producing characteristic deformity. (9) Duodenal ulcer; this case was diagnosed as a stenosis of the pylorus by clinical methods. In the radiograph the lesion was found to have been primarily in the duodenum, in its first portion, and secondarily to have caused dilatation of the stomach. In many of these cases of duodenal ulcer there was hyperperistalsis and beginning dilatation present. (10) Normal colon of an adult. (11) Congenital dilatation of the colon occurring in an infant three or four years old, the so-called Hirschsprung's disease or congenital dilatation of the colon.

---

**Sputum and Blood Cultures in Lobar Pneumonia.**—T. W. Hastings and E. Boehm note that typical cases of lobar pneumonia, in which no pneumococci are to be found either in the blood or sputum, probably exist more frequently than is generally supposed. These cases are not to be distinguished from the pneumococcus group except by blood and sputum cultures. *Streptococcus hemolysans* (*longus*) is an organism which may give rise to such a case. Schottmüller isolated *Streptococcus mucosus capsulatus* from the blood in a case of croupous pneumonia. There is probably no prognostic value in the bacteriological findings in lobar pneumonia.—*Journal of Experimental Medicine.*

# State Medical Licensing Boards.

## STATE BOARD EXAMINATION QUESTIONS.

### Tennessee State Board of Medical Examiners.

*May 1 and 2, 1912.*

#### ANATOMY.

1. Name the bones that form the wrist and hand.
2. Name the bones, which, when joined together, form the shoulder-joint.
3. Describe the sternum and give number of bones connecting with it.
4. Name the muscles that flex and extend the arm at elbow-joint.
5. Describe the nasal fossæ.
6. What bones erter into the formation of the nasal fossæ?
7. Name the articulation of the occipital bone.
8. Give a general classification of bones, and describe each class.

#### PHYSIOLOGY.

1. Define the terms (a) osmosis; (b) endosmosis; (c) exosmosis.
2. Describe ovulation.
3. How are the different sounds of the heart produced?
4. Name and describe the salivary glands.
5. Describe the act of micturition.
6. What constitutes a reflex act? Give an illustration.
7. How is audition accomplished?
8. Describe the red blood-corpuscles; (b) the white corpuscles; (c) what is phagocytosis?

#### CHEMISTRY.

1. What is the usual composition of urinary calculi? Give the test for recognizing the principal ingredient.
2. What chemical reaction takes place when $H_2O_2$ is applied to sloughing wounds?
3. Give the chemical action of chlorinated lime in the disinfection of typhoid fever stools.
4. Describe your method of procedure in making a chemical examination of suspected urine.
5. Give an explanation of the formation of ammonia in the urine.
6. Give two chemical tests that you would use in water supposed to be contaminated by sewage.
7. Give the physical and chemical properties of hydrochloric acid. How is hydrochloric acid prepared?
8. Give tests for the purity of chloroform.

#### MATERIA MEDICA.

1. Name four alkaloids of opium, and dose of each.
2. Name three principal salts of potassium and dose of each.
3. Name three medicines which act as galactagogues.
4. Name five drugs containing large quantities of tannic acid.
5. Name three of the most important mineral acids and give dose of each.
6. Name three medicines which produce rashes.
7. What are the effects of digitalis in medicinal doses?
8. What is the adult dose of the following tinctures: belladonna, aconite, valerian, veratrum, and hyoscyamus.

#### PATHOLOGY.

1. Describe a pathologic condition produced by excessive use of alcohol, other than its effect on the liver and stomach.
2. Describe a pathologic condition produced by tuberculosis, other than the lung.
3. Define torticollis, pleurodynia, hemiplegia, gastritis, and gastralgia.
4. Give the pathology of pellagra.
5. Describe the pathology of the tonsils and pharynx in diphtheria.
6. Describe the pathology of the mucous membrane of the large intestines in mucous colitis.
7. Describe the pathology of the large intestines produced by constipation.
8. Give pathology of acute pleuritis.

---

## ANSWERS.

#### ANATOMY.

1. *The bones that form the wrist and hand* are: The carpus (scaphoid, semilunar, cuneiform, pisiform, trapezium, trapezoid, os magnum, and unciform); five metacarpal bones, and fourteen phalanges.

2. The bones which form the shoulder joint are the scapula and the humerus.

3. The *sternum* is a flat, narrow bone situated in the median line of the front of the chest. It consists of three portions: the manubrium, the gladiolus, and the xiphoid process. At the junction of the manubrium and gladiolus is the angle of Ludwig, on a level with the second rib. It gives attachment to the pectoralis major, sternomastoid, sternohyoid, sternothyroid, triangularis sterni, diaphragm, and aponeuroses of the external oblique, internal oblique, transversalis and rectus abdominis muscles. It is connected with the clavicle and seven costal cartilages on each side.

4. *Flexion, at the elbow-joint is caused by:* Biceps, brachialis anticus, coracobrachialis, pronator radii teres, and the flexors of the wrist and fingers. *Extension is caused by:* Triceps, and anconeus.

5. The *nasal fossæ* are two irregular cavities situated in the middle of the face. They open in front by the anterior nares, and behind into the nasopharynx by the posterior nares. They are separated by the septum, which is generally deviated to one side. The mucous membrane lining the nasal fossæ is called the Schneiderian membrane. Each fossa has a roof, a floor, an inner and an outer wall. From the outer wall there project into each fossa the superior and middle turbinated processes of the ethmoid bone, and the inferior turbinated bone; these bony processes divide each fossa into a superior, middle, and inferior meatus. The nasal fossæ communicate with the sphenoidal sinus, the anterior and posterior ethmoidal cells, the frontal sinus, and the antrum of Highmore.

6. *The bones which enter into the formation of each nasal fossa* are: Nasal, frontal, ethmoid, sphenoid, vomer, palate, superior maxillary, lacrymal and inferior turbinated.

7. *The occipital bone articulates with:* Two parietals, two temporals, sphenoid, and atlas.

8. *Bones are classified* as: (1) *Long,* which consist of a shaft and two extremities, also called diaphysis and epiphyses; they are not straight, but curved. Examples are humerus, tibia, and phalanges. (2) *Short,* consisting of cancellous tissue covered with a compact substance; the carpal and tarsal bones belong to this class. (3) *Flat,* consisting of broad, flat plates intended for protection, such as scapulæ and parietals. (4) *Irregular,* such as vertebræ and ethmoid.

#### PHYSIOLOGY.

1. *Osmosis* is the diffusion of liquids through an animal membrane. The passage outward constitutes *exosmosis;* and the passage inward is called *endosmosis.*

2. *Ovulation:* "The ovisac, at first very minute, is embedded in the cortical layer of the ovary. Its wall consists of a layer of cells called the membrana propria, within which is found a second layer, the membrana granulosa. An accumulation of these cells forms a little mound called the proligerous disc, and in this the ovum is situated. These cells secrete within the ovisac an albuminous fluid. While the ovisac increases in size it also approaches the surface of the ovary, having then attained a diameter of one-fourth to one-half of an inch. At this point it stops growing, while the fluid continues to be secreted in its interior. This finally subjects the ovisac and the overlying covering of the ovary to a bursting pressure; the ovisac is ruptured, and the ovum, with some of the fluid and epithelium of the ovisac, is extruded upon the surface of the ovary." (Landis' *Obstetrics.*)

3. The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

4. The *salivary glands* are the two parotid, two sublingual, and two submaxillary glands. They are compound racemose glands, made up of lobes, which in turn are made up of lobules, and each of these latter is composed of tubular alveoli or acini connected with a duct. The ducts from the various lobules join together to form larger ducts and these eventually combine to form the main duct of the gland. The *parotid gland* is the largest of the salivary glands, and is situated outside the mouth, below and in front of the ear: its duct is called Stenson's duct; it crosses the masseter muscle, pierces the buccinator, and opens in the mouth opposite the second upper molar tooth. The *submaxillary gland* is situated beneath the lower jaw, and its duct is Wharton's duct, which opens at the side of the frenum of the tongue. The *sublingual*

gland is in the mucous membrane at the side of the frenum of the tongue, and its ducts (ducts of Rivinus) open on the floor of the mouth near the frenum of the tongue.

5. "The urine trickles drop by drop down the ureters into the bladder, where it collects and gradually distends it. The exit from the bladder is opposed by the sphincter vesicæ, or, as some believe, by the elastic and muscular fibers of the urethra. The urine is expelled by the contraction of the walls of the bladder, more especially by the detrusor vesicæ, and is assisted when much distended by the contraction of the abdominal walls. Micturition is a reflex act but one which (with the exception of infants) is under the influence, if not under the control of the will. The mechanism appears to consist of an automatic center in the lumbar part of the cord, maintaining the constant contraction of the sphincter, a second center, which, when stimulated, excites contraction in the detrusor. These centers are antagonistic, so that an afferent impulse from the bladder excites the detrusor center, at the same time inhibiting the sphincter center. These centers are normally under the control of the will, so that, although an afferent impulse may ascend from the bladder to the centers of the cord and up to the sensorium, yet by an effort of will the sphincter center may be assisted and the detrusor inhibited, or *vice versa*. Thus when the bladder becomes distended an afferent impulse from the bladder reaches both lumbar center and the brain; if the opportunity is favorable for micturition the controlling influence of the will is removed, the reflex contraction of the detrusor taking place, assisted perhaps by the voluntary abdominal muscles." (Ashby's *Physiology.*)

6. *Reflex actions* are involuntary or unconscious movements due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve. *Example:* The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

7. "The waves of sound are gathered together by the pinna and external auditory meatus, and conveyed to the membrana tympani. This membrane, made tense or lax by the action of the tensor tympani and laxator tympani muscles, is enabled to receive sound waves of either high or low pitch. The vibrations are conducted across the middle ear by a chain of bones to the foramen ovale, and by the column of air of the tympanum to the foramen rotundum, which is closed by the second membrana tympani, the pressure of the air in the tympanum being regulated by the Eustachian tube. The internal ear finally receives the vibrations, which excite vibrations successively in the perilymph, the walls of the membranous labyrinth, the endolymph, and, lastly, the terminal filaments of the auditory nerve, by which they are conveyed to the brain."

8. The *red blood-corpuscles* are biconcave discs, about 1-3200 of an inch in diameter; they are nonnucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin. They carry oxygen from the lungs to the tissues. The *white blood-corpuscles* are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes; (2) large mononuclear; (3) transitional; (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain: it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

*Phagocytosis* is the faculty of certain cells (notably the mononuclear and polynuclear leucocytes) to take up and destroy bacteria and other cells.

### CHEMISTRY.

1. *Urinary calculi* are usually composed of uric acid, or acid urates. *Test for uric acid:* Moisten a piece of the dust from a section of the calculus with nitric acid, and then with ammonium hydroxide; a purple color denotes the presence of uric acid.

2. In the presence of pus hydrogen dioxide effervesces, in consequence of the liberation of oxygen.

3. Free chlorine is released from the chlorinated lime and it kills the bacilli and their products.

*An analysis of urine* includes: Estimation of total quantity passed in twenty-four hours, color, odor, reaction, specific gravity, total solids (by aid of Haeser's coefficient). Then examine for albumin by Heller's test, or by heat and nitric acid; then for glucose, by Moore's test, with potassium hydroxide, or with Fehling's solution, which contains copper sulphate, sodium hydroxide, and Rochelle salt; then for blood with potassium hydroxide solution; then for bile pigments by Gmelin's test; then for indican, using lead acetate, hydrochloric acid, ferric chloride, and chloroform. Then quantitatively for urea, using solution of sodium hypobromite; for chlorides, with silver nitrate solution; for sulphates, with barium chloride solution. Microscopical examination should then be made for casts, cylindroids, crystals, and tubercle bacilli.

5. The ammonia in the urine is believed to be derived from that part of the protein decomposition which has escaped conversion into urea.

6. (1) Nessler's reagent (saturated solution of mercuric potassium iodide in ammonia-free distilled water, rendered alkaline with caustic soda or potash) gives a yellowsh tinge to the water in presence of sewage.

(2) Add a small quantity of sulphuric acid and enough potassium permanganate to give the mixture a red color. On boiling, the solution becomes decolorized in the presence of organic matter.

7. *Hydrochloric acid* is a colorless gas, with a sharp penetrating odor, very irritant to the respiratory tract and skin; it does not burn in the air or support combustion; it reddens litmus, is very soluble in water, is a powerful corrosive, also a disinfectant and bleaching agent. It is made by the action of sulphuric acid upon sodium chloride:

$$H_2SO_4 + 2NaCl = Na_2SO_4 + 2HCl.$$

8. *Tests for chloroform:* "Chloroform should be tested for excess of alcohol by specific gravity; for hydrochloric acid and chlorine by shaking it with water, which afterward should not give a precipitate with silver nitrate; for aldehyde by heating with solution of potassium hydroxide, which should not be colored brown; for empyreumatic and other organic compounds by shaking with an equal volume of pure sulphuric acid, which should remain colorless; or by evaporation, when no residue should be left and no odor should be perceptible after the chloroform has been volatilized." (Simon's *Chemistry.*)

### MATERIA MEDICA.

1. *Four alkaloids of opium:* (1) Morphine, dose gr. 1/5; (2) codeine, dose gr. ½; (3) thebaine; (4) papaverine.

2. Potassium acetate, dose gr. xxx; potassium chlorate, dose gr. iv; potassium iodide, dose gr. vij.

3. *Three galactagogues:* Pilocarpus, castor oil (leaves applied locally), and strychnine.

4. *Five drugs containing tannic acid:* Nutgall, catechu, witchhazel, oakbark, and logwood.

5. Diluted hydrochloric acid, dose ♏xv; diluted nitric acid, dose ♏xxx, well diluted; diluted sulphuric acid, dose ♏xxx, well diluted.

6. *Three medicines which produce rashes:* Arsenic, bromides, quinine.

7. DIGITALIS. *Physiological action:* It is a gastrointestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels, and causes a rise in blood pressure, it also acts as a diuretic.

8. Tincture of belladonna, dose viij; tincture of aconite, dose ♏x; tincture of valerian, dose ʒij; tincture of veratrum, dose ♏xv; tincture of hyoscyamus, dose ♏xv.

### PATHOLOGY.

1. The excessive use of alcohol is very apt to produce *arteriosclerosis.* In this the subendothelial connective tissue of the intima of the arteries is thickened, and the media undergoes degeneration (generally fatty or hyaline). The muscular coat may be hypertrophied or atrophied.

The patches of degeneration may become infiltrated with lime salts, and thus nodules or large plates are formed.

2. *Tuberculosis of the intestine* may affect the ileum, cecum, or colon. The ulcers attack the submucous and mucous coats, and may even perforate. If cicatrization occurs stricture of the intestine may result. The ulcers are to be differentiated from those found in typhoid. The tubercular ulcer has its long axis at right angles to that of the intestine, and the edges are infiltrated and undermined.

3. *Torticollis* is a spasmodic contraction of the muscles of the neck, chiefly the sternomastoid and the trapezius.

*Pleurodynia* is a painful rheumatic affection of the intercostal or thoracic muscles.

*Hemiplegia* is paralysis of one side of the body (and of the opposite side of the face).

*Gastritis* is inflammation of the stomach.

*Gastralgia* is pain in the stomach.

4. The pathological changes in *pellagra* are neither definite nor constant. Atrophy of muscles, heart, liver, and pancreas have been found; the intestines may be ulcerated or contain parasites. The nervous system may show no changes, or there may be degenerative or sclerotic areas in the spinal cord; degeneration or round cell infiltration of some of the nerves may be present. Its origin is unsettled; protozoa and the eating of diseased maize are two of the theories to account for it.

5. In *diphtheria*, the pharynx and tonsils are usually covered by a false membrane which consists of a network of fibrin, round cells, connective tissue cells, Klebs-Loeffler bacilli, and streptococci; this membrane is removed with difficulty and recurs.

6. In *mucous colitis*, the mucous membrane lining the colon is thickened and the mucous glands secrete abundantly; later on atrophy of the mucous membrane occurs. A pseudomembrane may form and be discharged from the rectum as a cast of the bowel or in masses of mucus. Ulceration is sometimes present.

7. In *constipation*, the muscular coat of the descending colon may be hypertrophied, the whole colon may be distended, ulcers may be found in the cecum; on the other hand, there may be no pathological lesions visible. The cause of the constipation may produce lesions.

8. *Pathology of acute pleuritis:* "The first stage is marked by congestion and irregularly diffused redness of the membrane with scattered flakes of exudation. The second stage is characterized by the copious formation of lymph, which more or less completely covers the membrane, giving it a dull, cloudy, or shaggy appearance. If the inflammation ceases at this period, it is termed *dry pleurisy*. If the condition progresses an effusion is poured out into the pleural cavity, which may be serofibrinous, fibrinous, or purulent. The serofibrinous variety is most frequent and consists of a straw-colored fluid containing fibrinous flocculi, blood, and epithelial cells. Its quantity is usually rather large. When the exudate is fibrinous, the amount is small and the consistency is greater than that of the preceding. It undergoes organization quickly and gives rise to adhesions and pleural thickening. The exudate becomes purulent (empyema) only as the result of microorganismal infection. The effusion may become bloody in some instances as the result of ulceration (tuberculous or cancerous) and grave blood diseases. Displacement of the viscera is common in this stage; if on the right side, the effusion pushes the heart farther to the left; if on the left side, the heart is displaced to the right, the impulse often being seen to the right of the sternum. The lungs are also compressed and displaced upward and against the spinal column. On removal of the fluid they again expand, except in cases of chronic pleurisy, in which the adhesions interfere with the functional activity of the pulmonary structure. Absorption of the effused material is the natural sequence in most cases. Unabsorbed portions undergo organization, producing adhesions, which, in extreme instances may obliterate the entire pleural cavity. Sacculation of the effusion by adhesions is not uncommon, especially in purulent exudations in which the adhesions form an abscess wall. Varying degrees of adhesion of the opposing pleural surfaces are encountered, depending on the character of the exudate."

**Life of Connective Tissue Outside of Organism.**—A. H. Eveling performed a series of experiments which showed that connective tissue can be kept in a condition of active growth outside of the organism for more than eleven months, that its mass increases considerably, and its power of proliferation, after such a long period, is more active than at the beginning of its life *in vitro*.—*Journal of Experimental Medicine.*

CLINICS, DEPARTMENT OF PUBLIC CHARITIES

CALENDAR, APRIL, 1913

MONDAYS

| | | | |
|---|---|---|---|
| *City Hospital* | Surgery | Dr. Dawbarn | 2:30 P.M. |
| | Dermatology | Dr. Fordyce | 3:00 P.M. |
| *Cumberland Street Hospital*, Brooklyn | Surgery | Dr. Walmserf | 3:00 P.M. |
| | Laryngology and Rhinology | Dr. Stewart | 4:00 P.M. |
| | Oral Surgery | Dr. Shea | 4:30 P.M. |

TUESDAYS

| | | | |
|---|---|---|---|
| *Neurological Hospital* | Neurology | Dr. Byrne | 9:00 A.M. |
| *N. Y. City Chil. Hospitals and Schools* Randall's Island | Orthopedic | Dr. Ogilvy | 10:00 A.M. |

**Congenital Atresia of the Esophagus.**—W. P. Shukowsky and A. H. Bacon report the case of an infant that manifested a slight degree of asphyxia at birth and that was not able to perform the act of sucking. There was a persistent discharge from the nose of a tenacious grayish white secretion. Death occurred in forty-eight hours. At autopsy there was found a dilatation of the esophagus that terminated below in a blind pouch. This communicated by means of a slitlike fistula with the trachea.—*Archiv für Kinderheilkunde.*

## Miscellany.

**Certainty in Surgical Diagnosis and Treatment.**—As interesting as statistics of operation-series are details of the personal qualities of surgeons. A trained eye will note many little tricks of gesture in an operator, as well as the technical points which engage the attention only of the novice. In one's earlier days as assistant, one remembers having to endure from one's nominal "chief" a fusillade of questions, such as: "Do you think I have taken it all away?"—"Will that stitch hold?" These show only a fussiness and lack of self-confidence that ought to point to an early retirement into private life. Another type is the man who looks on the presence of spectators as furnishing an opportunity for giving an anatomical demonstration.

Spectators themselves forget their rôle and display a loquacity about totally irrelevant matters while the surgeon is trying to fix his attention on his immediate work. Surely the most priceless gift for a surgeon is certainty—in diagnosis and in technique. In the former, this by no means involves a lightning diagnosis. The impulse to fly at a new patient with a diagnosis in one hand and a scalpel or medicine bottle in the other, is one which every "house-man" has to overcome. The scientific opinion is that which thinks of all possible causes of the condition, admits one as the most likely, and is quite prepared to reconsider it on cause shown. Such an attitude contributes to justice, and lessens the risk of a totally unwarrantable reproof of an assistant for not having told the surgeon of something he may otherwise discover only at the operation—a fault which Kocher has never to blame. Again, it is entirely distinct from a habit of "hatching" cases. It has happened before now that a patient with fever and inflammation over the mastoid process has been allowed to continue in this condition for some days, merely because the prospective operator has not had the judgment to recognize that immediate operation is necessary. In technique, fussiness is shown by zeal for large incisions, whereas men like Roux of Lausanne, and Caird of Edinburgh, will content themselves with an aperture barely two inches long when they have to remove an appendix. It is possible that such a spirit is fostered by the English custom of having half a dozen nurses on the floor of the operating theater, to wait on the operators, and even on the anesthetist, when all ought to do as much for themselves as possible, to avoid sepsis and needless alarms.

There is a blatant type of operator whose irritability, or what is even more offensive, whose sudden anxiety to teach his house surgeon details, increases with his audience. Some men will become excited by any mishap, others remain stolid because they really do not recognize what is happening. It is possible to be concerned about a patient's condition without becoming ululatory. The ideal is to recognize when operation is necessary, to do it quietly, knowing what one has to do and where it must be done, and to avoid attending to other men's work. A nervous surgeon who was alarmed about his patient asked an unusually placid anesthetist, "Is she all right?" The answer, given in a marked drawl, was, "Yes! Why? What have you done?"—*Universal Medical Record*, February, 1913.

**Portrayal of the Blind in Japan.**—From earliest times the blind have been favorite subjects for the artist's brush, and portraits of the blind alone do much to reveal the standard of painting at various epochs. The subject was treated with great realism by the Greeks, but the most relentless realism was displayed by the Dutch painters. With the exception of the Dutch school, however, Japanese artists are, according to Professor Greeff, the most faithful portrayers of blindness in its many aspects. In an interesting paper he brings out many curious features of the life of the blind in Japan, and of their portrayal by Hokusa, who was born about the year 1759. He ranks in European opinion as Japan's greatest painter, yet he appears to have been ignored by his contemporary fellow countrymen, and to have died in poverty and obscurity. After middle age he issued a series of sketches representing life in Japan, and he depicted as many as twenty-four distinct types, among the blind. His vivid realism lays him open at first sight to the charge of caricaturing. But Professor Greeff thinks that such an interpretation is unjust, and that the artist has caught true, but possibly fleeting, expressions of the blind. Some appear happy and scarcely affected by their blindness, others bear the stamp of sorrow and resignation, others look stupid, and others again are portrayed as idiots. Their attitude, gait, and expression betray the action of a common affliction on characters of widely different type.

Massage is an accomplishment commonly acquired in Japan by the blind, whose sense of touch is naturally well developed; and, as massage has been in common use since the eighth century, the blind masseur is well established. Massage is to-day prescribed for almost every form of illness, and it is commonly employed after baths or exercise. It is therefore not surprising that even the smallest villages in Japan can boast a blind masseur, and that he has been frequently depicted in the exercise of this art. Professor Greeff reproduces two such scenes depicted by Japanese artists, who evidently have caught characteristic expressions of both the masseur and his subject. The former, in one sketch, wears an expression of grim determination as he apparently digs his elbow into the small of the back of his subject. The latter's quaint expression of resignation scarcely suggests pleasurable sensations. In the other sketch, the masseur's expression denotes extreme despair and exhaustion, while the fatuous and languishing expression of his subject suggests the placid contentment of a pig being tickled.—*British Medical Journal*, February 8, 1913.

**Changing One's Diagnosis.** — Sir Berkeley Moynihan once said that some surgeons seemed to think that it was a humiliation for them to open an abdomen, after making a diagnosis on reasonable grounds, and not to discover the particular condition which they had supposed to be present. He had himself no compunction in throwing his diagnosis aside as soon as it was found to be wrong and going in search of something else. And if any precedent was required it could be found in the example of Saul, who went in search of his father's asses and found a kingdom.—*Clinical Journal*.

**The Surgical Ligature.**—J. G. Mumford notes that Ambrose Paré never dreamed of claiming that he had invented the ligature. This was used by Galen and by many others in ancient times to control hemorrhage from wounds; but strangely enough the thought of controlling hemorrhage from amputation wounds seems to have occurred to none before the time of Paré.

### A SUMMARY OF THE ORIGINS, TRANSFORMATIONS, AND PRESENT-DAY TRENDS OF THE PARANOIA CONCEPT.*

BY SMITH ELY JELLIFFE, M.D., Ph.D.,

NEW YORK.

VISITING NEUROLOGIST, CITY HOSPITAL; ADJUNCT PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, POST GRADUATE HOSPITAL AND MEDICAL SCHOOL.

THERE was a time, in the history of this Society when psychiatric subjects were discussed almost as frequently as those of more strictly neurological interest. I therefore feel that in my choice of a subject from psychiatry as a presidential address I am not departing from the usages of this body, and inasmuch as there seem to be many indications of a marked interest in the subject of paranoia, I felt I might bring to your consideration some suggestions, old as well as new, which might prove of profit.

I have thought to give my address somewhat of a historical cast, feeling as I have done so that if I am successful in robing and disrobing the figures of ancient as well as of modern psychiatry, and in making them pass rapidly before you, it may serve to indicate, after all, how variable is what we are apt to call truth. Furthermore, I trust my review will serve to orient the present traveler in the field of psychiatry as to the drift of opinion to-day relative to the paranoia question.

It is almost trite to say that with each new generation newer methods of solving old problems arise, and that refinements in methods of analysis, with sounder syntheses result. Old lines fade away, new boundaries are run, and radical rearrangements are everywhere apparent.

This is as it should be, and is an indication of healthy mental activity, and in no field of psychiatry is this forward push more apparent than in the consideration of the paranoia domain.

Seen from one point of view, it might appear that my discussion is dealing with a subject the trend of the development of which is tending toward an elimination of the concept entirely. Like the famous snakes of Ireland; so with paranoias—one might almost say that "there are none." On the other hand, another present-day trend points in the direction of the unraveling of some most fascinating and highly important mental mechanisms, which play a large rôle in the psychopathology of everyday life. The paranoid character, if I may so speak of it, promises to offer a clue to the further elucidation of many important situations, and which, lying outside of the more restricted field of present-day paranoia, give me more justification for dealing with them than I otherwise might hope for.

I shall not occupy your time unduly with the psychiatry of antiquity; yet I would remind you that the term paranoia is even pre-Hippocratic. While I am not clear in my mind what Hippocrates meant when he used the term, yet I feel sure that he may have employed it other than as was his more usual custom, as a general term including "craziness," as a whole, and therefore synonymous with his general terms "mania," "melancholia," etc. He speaks of paranoia as being a kind of thinking, which was common to a number of psychotic pictures, and inasmuch as he employs it as present in his phrenitis, his mania, his melancholia, —which latter are not to be conceived of as in any sense corresponding to later-day symbolic symptom groupings—it would appear that he meant that the thought was "beside itself." It was delirious, delusional, deranged, mad thinking.

But contemporary poets made use of the term, in two instances at least, in an extremely interesting and suggestive sense, as explanatory of a type of thinking which lay behind conduct of a peculiar type—and not allied to the ordinary conduct of the mad man, as seen even in the phrenitis, the mania, or the melancholia of Hippocratic classifications.

In Æschylus' (756) "The Seven against Thebes," we read, chorus (740):

"For of the crime I tell
Of which of old, swift vengeance fell
Yet whose dead issue the third age doth wait;
When Laios 'gainst Apollo's will divine,
From Pythia's central shrine
Who thrice proclaimed the sacred oracle,
"Die without issue would'st thou save the State."

---

Yet he, by friends o'erpowered, perverse of mind,
Begat the proper woe.
In Œdipus, the parricide, who dared,
In field unhallowed whence he sprang, to
Sow, a bloody offshoot. *Frenzy blind*
In wedlock the infatuate couple paired.

In Buckley's translation we find the place translated as:

"T'was *phrenzy* linked the distracted pair."

And in Euripides' "Orestes," (821), the chorus, in lamenting upon the murder of Clytemnestra by her son Orestes, says:

"Oh, 'tis the slight
Of impious sophistry putteth for right
The wrong; 'tis the sinner's [andron paranoia]
*infatuate folly.*"

Here we see that the word "paranoia" was used in a sense quite apart from that which a too strict reading of Hippocrates might give it.

*Presidential address before the New York Neurological Society, February 4, 1913.

We also meet with the word in Plato, in Aristophanes, in Aristotle, here used more or less in the Hippocratic sense. But I shall not linger in these far off times. There are more pressing needs about us.

Celsus turned it bodily over to "Insania," thus making it synonymous with the old time conception that all madness was one.

Aretæus seems to have been the last of the ancients to use the word, and, as far as I can make out, he attaches to it a purely general significance.

We now pass through the long period of the medicine of the Monasteries, which extended from the second to the ninth century, the period of the school of Salerno, from 850 to 1200 A.D. The scholastic period of the thirteenth century, the prerenaissance quite to the middle of the eighteenth century before paranoia again appears as playing any rôle in psychiatric terminology .

These periods are not without considerable interest to the student of the history of general psychiatry. But we cannot linger with them. Under the influence of Plotinus, Porphyry, Iamblicus, and their followers neo-Platonism occupied the minds of physicians and philosophers. Roman culture, it is true, retained for many centuries the objective and empiric point of view of the ancient Greeks in medicine but by a gradual series of changes which one roughly speaks of as the influences of neo-Platonism, of Mithraism, of Manicheism, and of early Christianity, the vigorous and sound objective interpretation of the schools of Hippocrates, of Asclepiades, of Aretæus, and of Galen gave way to the silly fantastic superstitious series of speculations, in which stars, planets, fire, and water, angels and demons, were influences at work in causing mental disturbances. Thirteen hundred years was occupied in this wallow of crude interpretations, with here and there some suggestions of rational psychiatry. In fact, it was not until the middle of the sixteenth century apparently that the first attempts at a nosology of mental disorders was made by Felix Plater.

This is Plater's general scheme:

1. *Mentis imbecillitas:* Hebetudo, tarditus, oblivio, imprudentia.

2. *Mentis consternatio:* Somnus immodicus, carus, lethargus, apoplexia, epilepsia, convulsio, catalepsis, ecstasis.

3. *Mentis alienatio:* Stultitas, temulentia, amor, melancholia, hypochondriacus morbus, mania, hydrophobia, phrenitis, saltus viti.

4. *Mentis defatigatio:* Vigiles, insomnia.

Mania and melancholia, principally the latter, are the general terms used throughout this entire period as a general term for insanity, until the time of Vogel.

Just what led Vogel to pick up the term paranoia is not apparent. This was in 1772. He employs it in two ways. In the first place as synonymous with insanity as a whole—for we note that the science of mental disease still hung on to the unitary idea of all of these psychoses as one—a belief, strange to say, advocated by many English psychiatrists at the present day—but Vogel here spoke of the paranoiæ, in the plural, and then we find him trying to create more or less specific trends among the psychoses—a tendency which was largely due to the stimulus given by the work of Linnæus in natural history.

It was just about this time that that memorable work of this Swedish botanist, the "Genera Plantarum," appeared (1753). It would only be natural that its principles of classification and those followed in his "Species Plantarum" should receive a much wider application and be reflected in the work of the medical as well as of the biological sciences. This is the case, and we find the first indications of it in the field of psychiatry, in the work of Vogel mentioned.

Then came an efflorescent period. Binomial nomenclature ran wild, and the work of Linnæus himself, of Sauvages, Plocquet, Valenzi, and Cullen show hundreds of species.

Here are amentias, anoias, paranoias by the score, including much that was sensible, thus as in Sauvages:

Amentia senilis, seracis, a venenis, a tumora, microcephalia, melancholia, scytharum, anglica, tædium vitæ, mysanthropica, milesiana, cynanthropica. Paranoia here was delirious thinking.

1772—Plocquet's "Paranoia" included:

1. Paracope (delirium), with sub-titles: (a) Pathetica, (b) phronestica, (c) entomica, (d) encephalica, (e) hyperesthetica, (f) sympathica.

Such a complex synonymy could not possibly endure—especially as, it was based upon so many fanciful and even superstitious foundations, remnants of the neo-Platonistic decadence previously outlined, and by the beginning of the new century we find the whole structure crumbling—but the *term* paranoia still persists.

One can say that throughout this period it still retained much of its most ancient significance. It usually went with a confusional, delirious type of thinking. The French reconstruction by Pinel threw it out of court entirely. His sweeping reduction to mania, melancholia, and dementia, however, was too simple, and even in France within a generation one finds the cropping up of Esquirol's monomania—destined to cause so much disturbance in the clumsy medicolegal machinery.

But let us pause just a moment to glance at paranoia in its German dress, especially as seen in the work of Heinroth (1808), for here one finds the first approaches of that century old discussion, the chief reverberations of which still linger in our present day psychiatry.

All through the period of which we have been speaking, the mental faculties were thought of as consisting of the intellect and of the will. Aristotle had set his stamp upon this dual system, and it persisted until the later part of the eighteenth century, when Kant, following Mendelsohn's general suggestion, augmented it to a trinity in which the intellect, the will, and the feelings became the ruling psychological categories.

The psychiatry of Heinroth is largely Kantian in this respect. In his synoptical table, one gets an excellent idea of the drift of Heinroth's psychiatry. He retains "Seelenstörung" as his general class—synonymous with the "Paranoiæ" of Vogel. He then makes an Exalted, a Depressed, and a Mixed group—occurring with three genera of each, according to whether the Feeling, the Intellect, or the Will is affected.

The Feeling *Exaltations* include a "paranoia ecstasia."

The Intellectual Exaltations—Verrücktheit—are given the group name "paranoia." The Will Exaltations make up the "manias."

The Feeling *Depressions* are termed "melancholias," the Intellectual Depressions, "dementia," and the Will Depressions, "aboulias."

The Mixed forms contain *confusions*—in the narrow sense "paranoia anomala"; confusion with furor, "paranoia anomala maniaca," general confusion, "paranoia anomala catholica."

Here, I think, we can find the origin of most of the paranoias of the nineteenth and twentieth centuries.

The time at my disposal will not permit a more detailed following of the situation in these early years, even if it seemed advisable. Neither shall I attempt to correlate, nor to describe, the gradual transformations of the English, French, and Italian terms, corresponding to the forms of Heinroth. I should like to do this, for, although it is not altogether possible, it would show the influences at work in the gradual evolution of the situation up to the time when the recognition of general paresis, as a distinct type of mental disease, commenced to overthrow the unitary concept of mental disease, and to revolutionize the entire outlook.

Such a discussion would show that from the time of the appearance of Bayles' "Chronic Arachnitis," of Falret, Sr.'s, "Folie Circulaire," of Kahlbaum's "Katatonie," and Kahlbaum and Hecker's "Hebephrenie," a gradual shift in the entire viewpoint towards mental disease has been taking place, in which etiological and clinical factors have slowly supplanted purely psychological and monosymptomatic criteria.

At the beginning of this period we see excitement and depression as dominating monosymptomatic designations for "mania" and "melancholia." And the ruling psychological conceptions followed servilely the pigeon hole psychology of the feelings, the intellect, and the will.

We purpose, however, to keep to the paranoia trail, and it is a striking feature, apparently not duplicated by any other group of psychoses, that the paranoias, so-called, developed along two increasingly divergent lines—lines already apparent in the Heinroth skeleton.

In Heinroth's Mixed Excitements and Depressions, it will be recalled, that among the Intellectual disturbances was what he called Confusion. The Simple Confusions made up the "paranoia anomala"; when Combined with Furor, "paranoia anomala maniaca," and the General Confusions made up the "paranoia anomala catholica." This general path was one taken by many psychiatrists, particularly in later years by Mendel, and still later by Ziehen. Under this concept then paranoia symbolizes all of those patients with primary delusional ideas with hallucinations, chiefly of sight and of hearing. These might be acute or chronic.

A rigid adherence to this point of view then presents us with a situation, still retained but by few psychiatrists, that *any combination of delusions with hallucinations* would constitute a "paranoia." Thus delirium tremens is the purest type of an acute paranoia with Ziehen. Following this general trend, it becomes evident that artificial and temporary similarity—a cross section as it were of a psychosis—would be sufficient to constitute a diagnosis, *i.e.* a nosological conception, and so far as acute paranoia is concerned, the lion and lamb might occupy the same pen. Such an attitude of mind permits a rapid classification, which possibly would change from day to day, or from month to month, and confuse many issues of etiology, pathology, prognosis, and treatment. The acute paranoias, according to this notion, are conceived of in the crude classical sense, as in Hippocrates, as delirious, delusional, mad thinking. Thus, Ziehen says in his last edition (4, 1911), "paranoias are those functional psychoses whose chief symptoms are primary delusions or hallucinations. If primary delusions enter into the foreground of the picture, one speaks of it as a paranoia simplex; if hallucinations are the chief symptoms, it is a paranoia hallucinatoria. Acute and chronic forms are to be recognized." Such a definition presupposes the concepts functional and primary—both of which have no place in any experiential or pragmatic psychiatry. Thus, in the simpler types, the various amentias, largely made up of severe, often fatal exhaustion psychoses; polyneuritic psychoses, of alcoholic, diabetic, syphilitic origin; infectious psychoses of streptococcus, influenzal, typhoid, syphilitic origins find a place together. Delirium tremens is a peracute hallucinatory paranoia. The delirium of bromides, of lead, of cocaine, of chloral, etc., would fall into the same group.

It is not my purpose to criticise the position taken by Ziehen in this matter. I simply desire to sketch this trend of a situation that tends to place the symptomatological picture in the foreground, and to desregard other types of relationships. It permits an hysterical, epileptic, alcoholic, syphilitic, puerperal situation to be grouped under the same symbol, because they all show primary delusions and hallucinations.

Neurology is hardly yet free from similar modes of thinking. Paraplegia, hemiplegia, epilepsy are some of the symptomatic generalizations of this type still sleeping in the neurological camp.

Retracing our steps to Heinroth, in order to orient the second trend one finds the German words, Verrücktheit, Wahnwitz, Wahnsinn. Here are Heinroth's Excitements, chiefly in the Intellectual sphere, which made up the other chief group of the paranoias. It is the following of this path which leads us more or less directly to the present day controversies. It is here particularly that one finds the attempt to use the General Paresis concept of an entity in mental diseases. Insanity, as such, no longer exists in medicine. Insanity is a medieval concept, which, unfortunately, still finds an abiding place in law. Instead we have the concept of different psychoses in a sense comparable to disease pictures of other organs of the body.

I need not rehearse how vigorously the psychiatrists of the nineteenth century fell upon the old mania, melancholia grab bags. How from these old generalizations new forms were erected, some of more enduring value than others. I shall not repeat before this body how Falret, father and son, constructed the Periodic Manias, Circular Manias, and related forms, which later were drawn together by Kraepelin into his Manic-depressive concept. It would be useful to detail the early studies of Kraepelin upon the Exhaustion and Infection groups—which made a great inroad upon the miscellaneous manias of early psychiatry, and still called Mania by many of the English school.

The rise and fall of the various paranoia concepts during this time, is one of the most instructive features of historical psychiatry, and we shall confine ourselves to its consideration.

To pass over with only the mention of Heinroth's great contemporaries, Ideler, Jacobi (who insisted that *Tobsucht* was not an entity), Blümroder, and others, it is worth while to stop with Griesinger a moment, where we find two at least of Heinroth's chief groups, namely, Wahnsinn and Verrücktheit. By Wahnsinn Griesinger understood those states of exaltation with affirmative, expansive affect, with

We
phia
continual self overvaluation, with transitory extravagant and fixed delusional ideas. These he says are identical with Heinroth's "paranoia ecstasia," with Esquirol's Monomania, and may be found in the work of Rush, our American psychiater, under the title Amenomania. The majority of these cases, he said, end in dementia. Here are found the lovers of princesses, and of courtly ladies, or, the women dream of intrigues with Knights or Kings. Here are the Napoleons, the world reformers, millionaires, Gods and Heroes. From the fact that Griesinger speaks of certain of these cases ending in paralysis, I suspect certain paretics strayed into his records as suffering from this type of Wahnsinn, although he says, in another place, the paretic ideas of grandeur have much more irregular and weaker features than the true Wahnsinn's. The hallucinations present are chiefly of hearing and are not forgotten, but encourage and reinforce the delusional ideas. Theomania, erotomania, are applied to certain forms when the delusions are more set or specific.

He spoke of an acute onset like furor, and of a chronic course. Some get well, as if "scales fell from their eyes" (certain katatonics), but those that do not, stay permanently in states of marked exaltation and finally dement.

Griesinger placed his "Partielle Verrücktheit" and "Böldsinnigen" in a common group of "Mental Weaknesses." Together they made up the great mass of the patients who were to be found in institutions. He conceived of those patients as having "Partielle Verrücktheit" who showed striking fixed delusional ideas, which had developed more or less secondarily to what he called mania, or melancholia, or, as perhaps we might say to-day, following periods of acute excitement or depression. Monomania is a good term, he said, though not in Esquirol's sense. He said the careful study of these patients had been neglected. They developed their delusional ideas slowly, following the attacks of mania or melancholia. These patients gradually underwent a new state of psychical tonus. They developed a change of character. They were not normal men, plus a delusion—they were changed throughout. There was an apathy, a loss of all psychical reactions, an indifference, and a diminished energy of the will. They took no more interest in the external world, could neither love nor hate, and showed only superficial passing periods of excitement, of irritability. Hallucinations were extremely frequent. He spoke of those who walk back and forward in a cage, of those who rhymed, or those who habitually hummed a tune, or repeated a verse or movement.

I have selected Griesinger's paranoias since neither Reil, nor Jessen, nor Feuchtersleben, nor Fleming, all names to conjure with in the psychiatry of this period, give enough point to their descriptions to enable one to make any correlations with present day symbols.

While Griesinger's ideas were leavening German psychiatry, those of Morel were active in France. Morel practically admitted only two psychoses, General Paresis and "Insanity," and his idea of "degeneration" reigned supreme in French psychiatry, and had a great influence in fashioning English thought, while Laségue (1852), dubbing the "paranoia" of the Germans "delusions of persecution," gave the push to this monosymptomatic tendency which has always characterized English as well as American psychiatry.

The periodical literature of this period—*i.e.* from 1850 to 1880—is occupied greatly with lengthy discussions as to whether paranoia was to be regarded as a disorder of the intelligence, or of the feelings.

This psychological tendency, mingled with the Morel doctrines of degeneration, and the ideas of Falret and Kahlbaum of *entities* in psychiatry, provide us with the developments leading up to the actual present. I might almost say in a general way that one aspect of the present day situation, as exemplified in the work of Kraepelin, has arisen from the gradual development of the clinical ideas of Falret, Kahlbaum, and Schüle, while another aspect of the situation, which is being fashioned by the Freudian school, has come from the psychological trends which we have seen were roughly foreshadowed in Heinroth.

The concepts given in the text book of Krafft-Ebing, represent the full bloom of the paranoia period. Morel's "degeneré" here has full recognition in his "Psychical degeneration." Paranoia is now the symbol under which 80 per cent. of the asylum patients are grouped, and they are either Primary Paranoias—Sander's creation of a special and rare early type—and the Acquired, or later forms, with Persecutory and Expansive Paranoia as the chief sub-titles.

The Krafft-Ebing picture is all too recent to need much elaboration. It, like most of the writings of Krafft-Ebing, was repeated almost verbatim from edition to edition, and as there were many editions, and as Vienna was enjoying much popularity as a medical center in the eighties and nineties, the conception of his text book of 1889 became widespread.

The chief features in his delineation were: (1) Chronicity, (2) Hereditary Taint, (3) Constitutional Neuropathy, (4) Delusions and Hallucinations. These delusions were not founded on the basis of the affect life, as was seen, he said, in mania, and in melancholia, but are contrasting pictures to the confusional deliria, by reason of the methodical, systematic, and formally logical development of a delusional system, which goes on for years and years, and is incapable of correction, or of cure. Hallucinations are an integral part of Krafft-Ebing's picture—they are of touch, sight, taste, and smell, but auditory hallucinations are most frequent. Krafft-Ebing's paranoia patients did not dement, *save* following *intercurrent disease*, or *masturbation*, or *other psychoses*. He nowhere gives any details of how often these complications occur, and hence one is left to speculate regarding the prognosis so far as deterioration is concerned.

Persecutory Paranoia was his commonest type. So firmly has this monosymptomatic expression come to rule psychiatric thought, that ideas of persecution came to be almost synonymous with paranoia. We are all familiar with the description of this large and miscellaneous group of Krafft-Ebing, and also with its sexual, jealousy, and litigious sub-groups.

His Expansive Paranoias were largely taken over from the masterly study of Magnan, of the "Délires chroniques à l'evolution systematiques."

Here the familiar Paranoia inventoria, reformatoria, religiosa, and erotica are portrayed.

The paranoia of Krafft-Ebing is the paranoia of the average layman, the lawyer and the general practitioner of our own day. It is the concept that many present day psychiatrists find sufficiently valuable to permit them to refuse to modify it, but, like every other general notion in science, it has had its day;

it has served its useful purpose; and has given way to other trends, which now occupy the main arena in psychiatric thought.

It soon became evident that Krafft-Ebing's Paranoias were a large, illy-assorted group of very heterogeneous disease trends. His idea of mental deterioration being a secondary process following "masturbation," "intercurrent disease," "mania," or "melancholia" soon showed its insufficiency the moment the patient's psychosis was studied for a longer period of time. These "other things" were really parts of distinct disease processes. They were essential bits of one situation; they were not "secondary" elements which determined a deterioration of a paranoia. It was no longer a question of two diseases the moment that Kraepelin insisted on studying life histories instead of brief episodic expressions.

The plaint was raised, and I hear it still, "one has to wait until a patient dies before a diagnosis can be made." "Yes," the answer is, "that is just what has happened." Kraepelin watched and waited, and followed his cases to the grave, and the results he has thus far obtained has justified his point of view. They are of value in that one may forecast what is likely to happen better than ever one has been able to do it before, and moreover therapy has become less a matter of guess work.

The large group of paranoia now began to suffer rapid dismemberment, and, out of the mêlée, we recognize the groups of (1904) dementia præcox of Kraepelin, and paranoia. Nearly all of the hallucinatory types have gone over to the former group, with its hebephrenic, katatonic, and paranoid subgroups, while for the latter a much restricted concept has been retained.

It is unnecessary to suggest to this audience that the disease pictures of mankind have not changed. They have, in large measure, always been much the same as they are now. The external, anecdotal features—Marconigrams, wireless telegraphy, and the like—are only more up-to-date externalities of which a paranoid schizophrenic, for instance, may complain; quite analogous to the influence of the stars of his astrologically trained homologue in Babylon many centuries ago. It is not the real underlying psychotic picture that has changed—it is only the hypothesis used to explain it, or describe it, namely, the symbol that has changed. Or, the symbol is retained and arbitrarily utilized to envisage an analytical or synthetic revision of previous concepts. It is not a question of where are the "paranoias" gone. There never were any definite things, *i.e.* "paranoias," to go—there were only mentally constructed, artificial groups, corresponding to a purely intellectual symbol. One shifts one's point of view, and reassembles the material in a different way for purely practical purposes—namely, one by which society will be the gainer in its practical problems.

Most of us here have lived through the dementia præcox controversy. We still have the reverberations of "no dementia" and "not præcox," but such criticisms arise from too narrow a construction of the validity of a symbol to represent a group synthesis.

We have now come in our review to the period in which the use of the term paranoia is restricted to smaller and smaller groups of individuals, following Kraepelin in large measure.

Without expressing at this time the counterpoints in the discussion, it is my purpose briefly to state the latest Kraepelin position, which was outlined before the Society of Bavarian Psychiatrists in Regensburg, June 29, 1912.* Here he traces some of the ground we have gone over. He points out that it soon became apparent that the ideas primary and secondary had little significance. The content of the delusional ideas was of little value—persecution as persecution is not at all limited—it is found in all psychoses; even the fixity of the delusional system is not to be counted upon. He raises the question whether or not the term paranoia might not be abandoned entirely, but he is inclined to retain it as symbolizing those delusion-forming psychoses originating from internal causes, with an extremely chronic development of an intellectually produced, unassailable delusion, in combination with complete "retention of the integrity" of the personality. One sees at once how far we have travelled from the concept in which "transformation of the personality" was a necessary *sine qua non* of a paranoia. Kraepelin speaks of this not as a disease process, but as a variety of psychical teratological mal development, which shows itself as a reaction to the struggle with life. He points out a paranoid constitution which has a mixture of measureless self overvaluation and of suspicion.

For the most part these people are able to get along in society, though they come at times very close to the border of serious conflict. They may be reformers, discoverers, inventors, founders of religion, or statesmen, and they have sprung, they claim, from those of noble blood. Kraepelin grants that some of this type of person may be regarded, as Specht has claimed, as forms of a constitutional manic mood—a variant possibly of a manic-depressive psychosis. Many of the members of this Society have sparred in the legal ring over just such a situation in the person of a well known iron worker.

Again, it is possible to regard others in this group as latent forms of the Schizophrenia of Bleuler. They do not show the intellectual dilapidation that occurs in the schizophrenic. Naturally an analogous picture is not rare in dementia præcox, but the affect changes, the impulsive motor phenomena, the hallucinations, and the looseness and silliness of the delusion formation, which come to rule the picture, exclude this category of patients. A paranoid feeblemindedness is another group to be separated from this limited collection.

Kraepelin now erects a new symbol "paraphrenie"—unfortunately another old Greek term, used for almost as many mental pictures as paranoia. Under this concept he purposes grouping a number of his previous paranoid types of dementia præcox, whose relationship to dementia præcox he now would call in question. He still shows allegiance to Kantian psychology and the old Heinroth subdivisions, for in these patients it is largely the intellectual, rather than the emotional and will sphere that is affected. The personality suffers less change than in the dementia præcox patients. This group "Paraphrenie" is a purely provisional one, and time alone will decide, he says, whether it will be of value or not as a principle of group separation. His sub-groups are Paraphrenia systematica, Paraphrenia expansiva, Paraphrenia confabulatoria, Paraphrenia fantastica.

*Paraphrenia systematica* is Magnan's classical "délire chronique à évolution systematique," with the exception that Kraepelin takes out from Magnan's group some true dementia præcox cases, and

*Zeits. f. d. g. Neur. u. Psych. 11, 1912, pp. 6, 7.

those who show more than a mental enfeeblement. Paraphrenia systematica will not include profoundly dementing forms. These must not be considered as paranoias in his sense, since there are hallucinations, and there is a definite disease which leads to definite invalidism.

*Paraphrenia expansiva* is a term for a rarer type: apparently a truly feminine type. There are gradual development of ideas of grandeur, with mild excitement, loquacity, and occasional outbreaks. Ideas of persecution (visions) are subordinate. The conduct is usually orderly, and not continuously influenced by the delusional ideas. There is marked chronicity, with slight diminution of judgment, and more diffuseness, but no true dementia.

*Paraphrenia confabulatoria* envisages those individuals with delusions founded upon memory falsifications. The patients are orderly and clear, have delusional ideas of persecution and grandeur, associated with delusional experiences of the past, which they dress up and continually remake, adding new to old, all on a basis of memory falsification. The patients are usually active and approachable, but their general conduct is often influenced by their delusional interpretations. There is a gradual breaking down of the patient with increasing incoherency in the delusional ideas. Hallucinations are not present, there is no schizophrenic modification of the personality.

*Paraphrenia fantastica* takes in the majority of Kraepelin's previous dementia paranoides cases. These may be atypical præcox cases. He expresses the hope that anatomical data may avail to separate them.

Kraepelin then goes on to discuss other paranoid conditions, such as occur frequently in other psychoses. He lays stress upon such states as are found in the manic depressive, senile, and presenile and toxic paranoid states, such as cocainism, alcoholism, tabes, certain syphilitic psychotic states. Paranoid prison psychoses are mentioned, paranoid psychoses of the deaf, paranoid mental contagions, and finally a group of the litigious or querulants, so well written upon by Serieux and Capgras. I must limit my discussion to this bare outline of his recently expressed views.

And now in conclusion let me briefly sketch the development of a paranoia concept, along entirely different lines. These are trends that show less interest in the psychotic picture—they seek if possible the genesis of the condition. Not how does it look and what shall we call it—but, how did it come to be, and what can we do for it? Can the condition be understood in terms of dynamic agencies; is its development comprehensible; and must it necessarily go on to the final ends which present day descriptive psychiatry is foretelling?

There have been attempts at dynamic explanations. Sophocles and Euripides involved the Brown Furies. The devil of the Middle Ages loomed large in the psychiatry of this long submerged period. A recent District Attorney of New York City declared that thrashing would drive out the "evil of a mind diseased."

The dynamic, or genetic conceptions of the Freudian school, were first foreshadowed in an interesting study appearing in 1896 (on a patient suffering from what he termed a chronic hallucinatory paranoia).* Freud first enunciated here the idea that this type of case may represent a form of defence to painful reminiscences, and the content of the psychosis, *i.e.* the clinical picture, is determined by the content of the repressed painful ideas. Special forms of displacement or distortion probably have to be sought for, and Freud believed he saw in this patient processes allied to the defence mechanisms found by him in the Compulsion Neuroses. The initial reproach—usually resulting from certain infantile foolish actions—often of a sexual nature—becomes repressed through a primary defence—often of self distrust. The return of the repression then determines the content—voices—hearing one's thoughts read or spoken. The secondary defences, such as appear in the compulsion neuroses, *i.e.* the compulsive thinking, ties, acts of touching, etc., etc., did not show in this patient, but there resulted a transformation of the ego as a reaction compromise. He did not pursue the question further at this time, but this work supplied the stimulus and gave direction to the studies of Bleuler, Jung, and Firenczi, which have resulted in the masterly synthesis of Schizophrenia, and the development of the psychanalytic method for the study of the psychoses.

The necessarily summary character of this address precludes the laying down of the steps which made it possible for Freud to outline at greater length his conclusions regarding paranoid mechanisms as shown in the now celebrated case of Schreber, the one time President of the Senate of Saxony.* And furthermore, I regret that I can only give you a very fragmentary condensation of the situation as he sees it. To obtain an adequate grasp of the mechanisms at work one must read the Schreber case. Furthermore, Bjerre's excellent résumé of a four months' psychanalytic treatment of a paranoid condition of ten years' duration should be read and re-read if a true estimate of this trend of thought relative to paranoid states is to be obtained. This therapeutic victory, over a disease process which has been so resistant to all therapy in the past, marks a milestone in psychiatry.

Bjerre, in discussing the theoretical aspect of his case, first accepts the Bleuler-Jung hypothesis of the "complex." But the relationship of the buried complex alone to the rest of the personality is not enough, he says, to explain the whole situation. Other mechanisms are at work. There were an unusually marked "male protest," marked sexual repressions, strange sublimations, and also some peculiar constitutional anomalies. The repressions which he worked out are considered in a strictly Freudian sense. Freud has thought to show that, varying with the mode of handling these repressions one can posit certain reaction types. If the repressions are *converted* into bodily symptoms, the well known hysterical reaction type appears; if *substitutions* and defences are resorted to, one has the obsessional, compulsive type of reaction, while if the repression is of a certain type and is handled by an outward *projection*, one speaks of it as a paranoic reaction type.

This projection, Freud suggests, takes place in somewhat of the following manner: An inner realization, or perception, is suppressed, but apparently must come into consciousness and be disposed of in some manner. When this handling takes place, it is by a process of disfigurement or distortion, as a perception from the outside world, and then one speaks of it as a delusion. A delusion of persecution, for instance, then is to be read as a disfigurement or a distortion of a love impulse, which love

*Neur. Centralblatt* XV, 1896, p. 442. "Nervous and Mental Diseases, Monograph Series," No. 4. Second Ed., 1912, pp. 165-174.

*Jahrbuch für Psychoanalyse, Vol. III.

becomes impossible for reasons peculiar to the individual and his cultural, ethical standards. The love then becomes transformed into hatred, and is projected upon the outside agent. There is, in Jung's phraseology, a projected negative transference.

Why is it that love becomes impossible, and must suffer a negative transference as hatred? This in Freud's view is apparently the crux of the situation. For him it is because of the unconscious existence of an accentuated homosexual component in the personality of the particular individual who shows a paranoid type of reaction.

It may be recalled that, in his "Three Contributions,"* Freud attempts a sketch of the normal psychosexual evolution of human beings. The term "autoerotic" symbolizes one of the large phases of this evolution towards a normal heterosexual development. This phase or period occupies much of the so-called "latent period" in childhood, and is divisible into a number of periods—the Narcissism and the homosexual period being most characteristic. These may be recognized as intermediate stages, which some individuals never pass beyond. They remain attached or fixed in smaller or larger part to these developmental stages.

In the average individual the homosexual component finds adequate outlet in friendship, in companionship, in the altruistic feeling for humanity and its common good. Those who cannot rise completely out of Narcissism, and are thus prematurely fixed or arrested in the evolution of their psychosexual disposition, are exposed to the danger that a flood of energy, which finds no outlet (thus the frankly homosexual, in the vulgar sense, rarely suffers) sexualizes their social tendencies, and causes the sublimations which culture has evolved, to be reversed.

The results of those analyses thus far obtainable point to the fact that the paranoid patient is engaged in a struggle against the sexualization of his social tendencies, and that he has a *locus minoris resistentiæ* in his autoerotic, narcissistic, or homosexual phases.

There may therefore arise several possibilities in the paranoid type of thinking. Thus the paranoid erotomaniac endeavors to evade the issue—he is unable to say "I do not love *him*"—a homosexual object—but, "I love *her*, to devotion," which by a process of projection becomes—"She loves me."

A male paranoid is in an unconscious struggle with the dimly perceived, or instinctively-felt longing for another man. His defence is the conscious projection of being hated, being persecuted by the man. The love which must not be permitted to exist is distorted into the hatred which he must feel for one, who at one time was much admired, but who now projectively persecutes him.

It is not needed that I go further into this situation by further examples of the paranoid distortions that take place in the delusions of jealousy so frequent, for instance, in alcoholic paranoid states. Here the reductions of cultural, sublimation processes induced by the alcoholism, raise the homosexual possibilities nearer to conscious perception, and thus there is established an active need for a defence reaction. It shows itself as a jealousy directed against the woman, and a projection in which the males become loved by the wife.

Freud soon met with the experience that the projection mechanism alone was not a sufficiently pathognomonic mechanism to utilize as a diagnostic criterion. In fact projection may appear as a perfectly normal mechanism. We all use it every day. Much of our dislike for our fellow men is projected as faults which we assume they possess. When, however, projection appears with the autoerotic fixation, the after active repression, or negative transference, and a final failure or breaking through of the repression into consciousness, there to be handled by projection—then one has the paranoid type of thinking.

It would be a fascinating program to endeavor to fit the various clinical series, which have been outlined as Kraepelin's latest deductions, with the general mechanisms here briefly outlined. For even as now understood there are enough variants, particularly in the autoerotic fixations, to permit an attempt at such a series of correlations. Freud views the whole delusional dynamic as one of reparative value. It is a reconstructive or healing process. Those who seem to come off best in the fight, it may be suggested, are apparently the simon pure paranoias of Kraepelin, so far as dilapidation of the personality is concerned. Here the regressions only sink to those auto-erotic phases most closely allied to present states of culture. Should the regressions sink lower, however, the distorting projections are more violent, and the personality suffers more. These are, I may suggest, the various Paraphrenias of Kraepelin's scheme. Whereas, if the regressive libido sinks to the lowest levels—if it is withdrawn entirely from the outside world, *i.e.* if the conflict between instinct and ethical standards demands the sacrifice of the sexuality entirely, then there is nothing but death, either by suicide or by the withdrawal of the individual from the real world into a world of phantasy. Here the mechanism spells dementia præcox; in its hebephrenic form an unconditional surrender; in its katatonic types with periodic stormy protests and violent cataclysms, out of which occasionally the patient comes into reality, having fought out in the delirium its deliverance from some phase of its soul conflict.

## SURGICAL CONDITIONS OF THE ABDOMEN IN THEIR RELATION TO LIFE EXPECTATION.*

By MORRIS BOOTH MILLER, M.D.,
PHILADELPHIA.
PROFESSOR OF SURGERY, PHILADELPHIA POLYCLINIC.

In these days of rapidly advancing progress in surgical endeavor, when dreams of wondrous cures come true at the almost magic touch of the aseptic scalpel, when the domain of the internist is constantly and successfully being invaded by the surgeon, when living pathology is a fascinating reality and not a meaningless word, when men on every side are capable of solving difficult diagnostic problems and then of applying soundly and skillfully the needed operative measures, it is well to pause to note the sum total effect of all of this remarkable advance upon human expectation of life. In a general way we realize that great good has been accomplished. The growing popularity of surgery in the public mind stands upon the firmest of foundations—actual achievement. While definite and specific datum is not easy to secure, the broad evidence is eloquently presented in our vital statistics which show that human existence is appreciably

*Read before the Philadelphia Medical Examiners' Association, February 4, 1913.

lengthened decade by decade. Beyond a doubt preventive medicine is entitled to the first honors in this accomplishment, but surely next in order must be placed surgery, using the term in its widest acceptation; and when we add to the longer span of years, the decrease of pain and suffering and the consequent increase in human efficiency, the aggregate result becomes tremendously impressive in its magnitude.

The purpose of this paper, however, is not to pay tribute to surgery nor to hazard a prophecy as to its doubtless brilliant future, but to present to you certain generalizations, derived from surgical experience, which are applicable to life insurance examinations. It is, of course, impossible to specifically deal with any question concerning so uncertain a matter as the future, but just as the wise investor bases his judgment of the security of his investments upon past earnings, so it is possible for us to shrewdly estimate what an individual's expectation of life may reasonably be after we have closely investigated all phases of his past and present physical condition, and inasmuch as there are frequently arising problems which depend for their correct solution upon some appreciation of the surgeon's point of view, such as a latent surgical lesion the recognition of which is not easy, or the permanency of cure after operation, or the effect of operative procedures upon the general health, a short summary of the generally accepted opinions upon some of the commoner surgical conditions may prove acceptable. Of necessity my contribution must be incomplete and fragmentary in discussing so large a subject within reasonable limits.

Before taking up the few topics I have selected for discussion I wish to urge, with all the emphasis I can, a greater diligence and care in the methods employed to arrive at a sound conclusion as to insurability. Too often it happens, in my experience, that conditions which would have a material bearing upon the final judgment are either undiscovered, or, if noted, are glossed over as being relatively unimportant. It must be borne in mind that in modern diagnostics we are in a period of transition in which the older methods of physical diagnosis in many instances are being supplemented, or, indeed, sometimes supplanted by laboratory tests of tried and sterling worth. Forsooth, what hospital of today would assume to identify malaria without a blood examination or syphilis without a Wassermann? The lay public has learned to respect the ophthalmoscope, the stethoscope, and the clinical thermometer, but it has not yet come to the point of accepting with equanimity and conviction our routine examinations of the blood, of the employment of blood pressure apparatus, of the use of the Röntgen ray in other conditions than that of fractures, of the cystoscope, and of various other modern procedures the whole object of which is to make diagnosis more and more precise.

Of first importance in forming a sound conclusion, especially in abdominal conditions, is a good history. Only a few days ago I heard it stated in open discussion that the general practitioner never bothers to take a history. Personally I cannot believe that such neglect generally obtains. Certain it is that in life insurance work a history is always required, but it has seemed to me that sometimes it has been too circumscribed, too often bound down by the formalism of printed questions which must be answered, and not often illuminated by the searchlight of high intelligence. To secure a satisfactory history is a matter of tact and time, coupled with a keen appreciation of the relative importance and significance of the facts elicited. To illustrate my point I may mention a circumstance which occurred in Philadelphia not long ago. A physician of international reputation was called in consultation from a neighboring city to see a prominent man who was acutely and seriously ill of an obscure abdominal disease. He devoted just an hour to the development of a painstaking and thoughtful history, about five minutes at the bedside, and then stated in tones of conviction that the disease was acute pancreatitis. Operation was immediately done, the diagnosis confirmed, and the patient recovered.

In the actual examination of the applicant for life insurance insufficient attention, as a rule, is paid to the abdomen. Much may be learned by systematically inspecting, palpating, percussing, and, indeed, auscultating the belly. To the trained observer it is an interesting region from flank to flank, from the umbilicus to the posterior layer of the perinephric fascia. While slight variations of location of some of the abdominal viscera are entirely compatible with perfect health, yet the boundaries beyond which organs do not go without indicating disease should be clearly recognized. The margins of the liver and spleen are usually outlined in routine examinations but how often are the kidneys investigated save by urinary examination? The normal situation of the gall-bladder, the appendix, the pylorus, the cecum, and the sigmoid should always be kept in mind and these areas carefully palpated. In the absence of bismuth meal skiagraphs we can still do something in determining the size and location of the stomach, colon, and small intestine by closely observing the pitch of the percussion note as it varies with the different calibres of the alimentary tube. Even the anterior abdominal wall may be highly suggestive of intra-abdominal disease. Inequality of muscle resistance, alteration of abdominal reflexes, dilation of the superficial venous tracery are three factors, among others, which are never without significance. But these are merely a few suggestions, and many others will doubtless occur to you.

One of the most interesting of intraabdominal diseases is that of appendicitis. As far as its acute forms are concerned it is obviously not a subject for consideration by the life insurance examiner. However, not infrequently questions arise as to the insurability of, first, the individual who has had an attack of acute appendicitis but who has recovered without operation and in whom there may or may not be indications of appendiceal irritation; second, the individual who has definite signs of local tenderness at the time of examination or whose history shows transitory attacks of the so called appendiceal colic, and, third, the individual who has undergone operation.

As to the first question it may be stated axiomatically that a patient who has had one attack of appendicitis is always liable to another unless the appendix has been removed. This liability is proportionately greater if, by reason of the first attack, there is left ulceration, or narrowing or blocking of the lumen at any point. Fortunately these changes give rise to a palpable and tender appendix, at least at times. Naturally such a patient cannot be considered a good insurance risk under any circumstances and should be advised to undergo an interval operation, an operation which,

as you know, carries with it substantially no mortality in the hands of a competent operator. Now and then there are cases which are seemingly well during the interval but a second, or yet a third, attack, finally points the way to the operating table. Like every good rule there are occasional exceptions to it, and every physician of wide experience has seen a few instances where an attack, usually a mild one, has completely cleared up and the patient has remained exempt throughout the rest of his life. The obvious impossibility of picking out these rare exceptions leaves us no alternative to our ordinary advice.

As to the second question I have already indicated my views with respect to the patient who has a tender and palpable appendix at any time and a history of a previous attack of acute appendicitis. Sometimes you will meet an appendix subject to a low grade, catarrhal infection. It is usually characterized by occasional twinges of pain, frequently vague digestive disturbances and constipation, now and then a little local tenderness, but never fever nor vomiting, and never any serious manifestations. Sooner or later there is an overgrowth of connective tissue fibres and by process of cicatrization there is a gradual obliteration of the blood vessels, lymphatics, and the epithelial elements. It is the type of appendicitis in which the patient diagnosis his own malady and lets you know all about it in tiresome detail. Dr. Robert T. Morris has delightfully, though metaphorically, described it as the form in which one end of the appendix is attached to the cecum and the other to the cerebral cortex. Practically it has no mortality and as such might be acceptable to the insurance companies, but the general impairment of health due to the digestive derangements and to the associated mental perturbation makes it highly desirable that operation be done. As a matter of fact my experience has been that patients having obliterative appendicitis are only too willing to submit to the knife.

On the question of judgment in accepting for insurance postoperative cases I have a suggestion or two to make. In an otherwise healthy person who has been operated on during an interval or at an early period of an acute attack, in brief the ordinary case which is closed without drainage and in which there have been no complications, I can see no reason why such a person should not be taken as a first class risk, provided always that at least three months shall have passed since the operation. My reason for this short delay is because there is a remote possibility of incisional hernia occurring within that period but not later.

It is in the cases where abscess has occurred, or general or diffuse peritonitis has been present, the cases of necessitous drainage, that we are sometimes in considerable doubt as to the probable future state of health. Sound judgment here is only possible with the fullest information about the acute attack. Fortunately, as a rule, this is available through hospital records, since these cases are almost without exception treated in a hospital. Perhaps the first question to be determined is whether the appendix has been removed. The consensus of surgical opinion is decidedly in the direction that an unremoved appendix, or even an appendiceal stump, may relight in inflammation at some future time. The older idea that the appendix always sloughed away and gave no further trouble has been shown to be erroneous. Coley concluded after investigating a large number of cases that about 20 per cent. recurred. Another phase worthy of inquiry concerns the extent and character of the adhesions. These are important in their bearing upon disturbed intestinal motility and particularly upon the future liability of obstruction, either acute or chronic. While it is not possible to accurately gauge postoperative adhesions something may be surmised by learning the extent and direction of the infection, the character of the drainage and its duration, and perhaps the bacteriological findings. Secondary operations for residual abscesses, for obstruction, or for any other cause not only raise the immediate mortality rate but also increase the chances of future morbidity. As a matter of fact, it has been amply demonstrated by autopsy and by operation for other subsequent conditions that the primary adhesions of the average operated case largely disappear in the absence of continued infection. Mumford says that 94 per cent. are ultimately well, while only 6 per cent. show by pain or other phenomena the presence of disturbing adhesions. There is, however, in all drainage cases a distinct liability to acute obstruction within a period which may be roughly put at about two years after operation.

Finally it must never be forgotten that the scar resulting from appendiceal drainage, no matter where placed, is a weak one and singularly liable to hernia, and, furthermore, that incisional hernias are apt to become dangerously strangulated.

In summing up I would advise the acceptance of a person who had been drained for appendicitis provided two years had elapsed during which no obstructive or painful phenomena had occurred, no hernia was then present, and it was affirmatively shown that the appendix had been removed in its entirety.

With reference to ordinary hernia I am told that the usual practice of the insurance companies is to accept men so affected if they agree to wear a truss. It would seem that this attitude represents a compromise forced upon the companies by the relative frequency of the condition, a compromise in which business has had a voice. Surgically speaking, every man who has a hernia is materially substandard in physique and the wearing of a truss is only a precautionary measure which is often sadly inadequate. I am under the impression that personally I have operated for strangulation more often on truss wearers than on non-truss wearers. The truss does good and apparently accomplishes many cures but this is always prior to the 20th year. Between the 20th and 40th years, in the period of life when radical cure can be done with ease, safety and success, it may prove competent but frequently does not. After the 50th year, despite its use, there is a progressive likelihood of inflammation, incarceration, or strangulation.

The risk in ordinary reducible hernia must be estimated purely from the basis of possible complications, since there is no impairment of the general health incidental to its presence. Assuming that the present ruling holds it is still thoroughly worth while to verify the simple character of the rupture. The possession of an inguinal hernia of unusual size, or of one which frequently eludes the truss, or of one which can only be reduced with effort or pain, or of one which has omental or intestinal adhesions in the sac or even to the margins of the hernial opening, would in my judgment serve to disqualify; and further it might always be well to thoughtfully weigh such collateral facts as occupation, personal habits, and usual habitation in their

relation to that particular hernia in that particular individual before deciding affirmatively.

In passing, attention must be called to the frequency with which maldescent is seen associated with hernia and to express an opinion that such cases are not insurable on account of the well-known tendency of the undescended testicle to sarcoma, as well as for other causes.

Femoral hernia carries a somewhat greater risk than inguinal hernia. The control exercised by a truss in the femoral region is far less certain and satisfactory; strangulation is distinctly more apt to occur and is decidedly more liable to be followed by fatality. And, finally, some forms of hernia should always be declined on account of the unusual or undeterminable risks. I refer to umbilical in the adult, incisional, and the rarer forms like interstitial, sciatic, gluteal, and others.

The postoperative phases of hernia may be dismissed in a few words. As is perfectly well recognized, the modern radical cure is one of the most certain and satisfactory operations known. It has a theoretical mortality of one-quarter of one per cent., practically amounting to nothing, while the chance of recurrence varies from 5 to 8 per cent. The latter sometimes can be anticipated at the time of operation, for example, failure is apt to follow wound infection, but this is not always true and now and then a recurrence is seen without ascertainable cause. However, in the vast majority of cases a relapse, if it is going to occur, will be apparent within six months. Strangulated hernia, or hernias in which there are any unusual features, show a much higher percentage of relapses, and it should always be remembered that with the former secondary operation for obstruction is not infrequently necessary.

In turning our attention to the upper abdomen we approach a region which holds deep interest for all of us. While a huge mass of literature upon the various surgical conditions of this area is available on almost every question which concerns us as practitioners of physic yet when a search is made for specific information to guide us in estimating the remote effects of surgery in relation to life expectation we are disappointed by the meagre material at hand. The reason for this is not far to seek. As we know active interference in the upper abdomen has been extraordinarily successful in its immediate life saving results, but when it is recalled that this has only been true within the last ten or fifteen years, when many of the more important operative procedures have been placed on a sound and generally accepted basis, it is not strange that insufficient time has elapsed to give us a proper perspective in this direction. It is therefore only possible to venture opinions in a conservative and tentative manner. From other possible topics I have selected for brief consideration two groups of disease in this neighborhood, the gall-bladder in its relation to infection, and ulcer of the stomach or duodenum.

The symptomatology of chronic or latent disease of the biliary passages is too complex and difficult for casual presentation and therefore in this paper I shall strictly confine myself to some remarks upon the postoperative aspect. It is singular that with the immense literature now at our disposal there are very few papers which deal with end results in a comprehensive and instructive manner. Kehr, McWilliams, Taite, Monroe, and, more recently Stanton, are notable exceptions who have furnished valuable statistics in this field. The latter, in a paper on "End Results in Gallbladder Surgery," published in the Transactions of the Surgical Section of the American Medical Association in 1911, has made a careful analysis of a large series of cases operated upon by Ochsner, McMullen, and himself. Substantially his conclusions coincide with those of the other writers I have mentioned.

Stanton divides his cases into those in which gallstones were found and those where cholecystitis was present but no gallstones were found. In the first group 79 per cent. were found to be entirely cured by the operation, according to the statements of the patients, while 6 per cent. reported themselves as well with a few minor discomforts, so that a total of 85 per cent. of good results may be reported. Of the remaining 15 per cent., 9 per cent. were improved and only 6 per cent. were doubtfully improved or no better than before the operation. In 2 per cent. secondary operations were necessary to accomplish cures, in 3 per cent. postoperative hernias ensued, and in 1 per cent. there was recurrence of calculi. Chronic pancreatitis was found in 4 per cent. and of these 90 per cent. were cured.

In the second group, that of cholecystitis without gallstones, the end results were anything but satisfactory. Only 46 per cent. of the patients reported themselves to be cured and 10 per cent. were classified as satisfactorily improved. With 23 per cent. there was improvement and in 19 per cent. there was no benefit or the patient was worse.

As might be expected in both groups the proportion of poor results was increased by associated visceral lesions elsewhere, and particularly was this true if the lesion was pelvic. Among all cases from all sources, numbering nearly 1,800, I have been unable to find one of carcinoma of the liver or biliary passages in which recovery has taken place.

It will be seen, therefore, that the permanent results of operations for the removal of calculi are perhaps as satisfactory as those seen in any important field of surgical endeavor. He who runs may read, and the life insurance examiner may very properly infer that the great majority of individuals who have been operated on for gallstones, and in whom after a reasonable lapse of time there have been no untoward phenomena, are perfectly acceptable for insurance. With respect to the operated cases of cholecystitis without gallstones, especially if there are other visceral lesions, an attitude of considerable wariness would seem highly advisable.

It is highly probable that at least one-twentieth of all mankind are affected at some time during adult life with gastric or duodenal ulcer. Between the ages of twenty and thirty it is apt to be acute and only involve the mucous membrane, to be more often seen in women, and its site is usually gastric; from thirty to fifty it is apt to be chronic and cause deep induration and adhesions, to affect more men than women, and the situation of the ulcer is more frequently duodenal. The area subject to ulceration is not extensive and a distance of six inches, with the pylorus at the center, will cover the great majority of all peptic ulcers. As a rule, the acute ulcer either disappears spontaneously or is readily curable by simple measures, and, as far as known, the resultant scar is innocuous. Exceptions occur but in the main a cured acute ulcer generally may be dismissed as a life insurance factor of importance. But with chronic ulcer the situation is vastly different and the subject is entitled to our careful consideration.

In no disease which presents such wide variations

of symptoms as chronic peptic ulcer is it possible to formulate the phenomena which will unerringly point to its certain recognition. Especially handicapped is the medical examiner, who is shortsightedly denied the opportunity of verifying his suspicions in this direction, by such valuable and oftimes conclusive measures as the bismuth skiagraph and the gastric analysis for blood, pus and hydrochloric acid. It is, therefore, incumbent upon him to develop the diagnostic faculty to the highest possible degree with the limited means at hand. Of these by far the most important is the personal history. Just as our suspicions of biliary duct disease should always be aroused by a history of typhoid fever, so should a history of chronic indigestion, especially a painful indigestion which may or may not have long periods of quiescence, direct our keenest diagnostic focus toward the area of the stomach and duodenum. In this connection it may be comforting to recall that in actual practice many cases of chronic ulcer are satisfactorily diagnosed by the history alone and with which the laboratory tests are only used for confirmation.

Let us briefly run over the more important symptoms in the average case derived from a good history. Pain is a very constant phenomena and occurs in nearly 95 per cent. of all cases. In gastric ulcer it referred to the epigastrium and may radiate to the left shoulder; it is increased by the ingestion of food, and is experienced from half an hour to three hours after eating. In duodenal ulcer pain is also felt in the epigastrium, with occasional referred pains in the back, but it occurs in definite cycles lasting a few days or several months with complete remission of all symptoms during the interval. It is most marked from two to five hours after eating. It is relieved, at least in part, by food, water, alkalies, or vomiting. To be awakened at night by pain which is quieted by the indigestion of a biscuit or a glass of milk is a story typical of duodenal ulcer, and quite as characteristic is the self-taught habit of using bicarbonate of soda to temporarily relieve the distress and burning pain. Epigastric tenderness in either form of ulcer may or may not be present and is only well marked in the presence of localized peritonitis. Vomiting is a prominent symptom in many cases of gastric ulcer and it usually occurs with some degree of regularity between one and four hours after eating. It is not so frequent with duodenal ulcer though it may occur irregularly and at intervals of three or four days. Gaseous and sour eructations and gastric distention are seen in nearly every case. Hemorrhage is common only in acute gastric ulcer, uncommon in chronic gastric ulcer, and very rare in duodenal ulcer save in an occult form. As a rule, loss of weight is slight, and any great reduction of weight should arouse strong suspicions of malignancy. Finally, neurasthenia in its minor phases is very frequently associated with chronic peptic ulcer, especially if it is on the duodenal side of the pylorus.

It is a matter of the utmost importance to sound insurance work that any form of this disease should always be recognized if it is humanly possible to do so. There can be no debate upon the question of the non-insurability in peptic ulcer, acute or latent. I would even go so far as to give as my personal opinion, that an honest suspicion of the presence of this lesion is sufficient grounds for a medical examiner to decline any applicant for insurance. To merely enumerate the serious and dangerous conditions which are liable to develop furnishes convincing argument in favor of this opinion. One possibility is hemorrhage, which may be constantly slight but enough to lead to serious anemia, or intermittent which may profoundly depress the vitality and lower the bodily resistance, or sudden and overwhelming which speedily results in death. Another is perforation, either acute and causing one of the most classic of abdominal tragedies, or chronic and giving rise to perigastric, subphrenic, or subdiaphragmatic abscess with a discouraging rate of mortality. In a third group may be mentioned perigastric adhesions, pyloric stenosis, or cicatricial distortions of the stomach, any one of which may seriously and permanently affect gastric function and lead to invalidism and death. A fourth possibility of indirect character is seen when von Mikulicz's statement is quoted that 20 per cent. of these cases die of pulmonary tuberculosis. And, finally, must be mentioned the relationship of chronic ulcer to cancer. Writers differ somewhat upon this point but all agree that gastric carcinoma has its origin in ulcer tissue in at least 5 per cent. of all cases of stomach cancer. My own view, unfortunately without much experience to base it on scientifically, is that it is very much higher. Only a few days ago Dr. J. G. Bloodgood, of Johns Hopkins, told me that out of thirty excised ulcers examined by him, none of which were suspected, he found in two commencing cancerous change.

Much, though not all, of this dire record fades into nothingness as the result of modern surgery. Precise statistics are wanting but it is probable that from 60 to 70 per cent. of all cases of peptic ulcer are permanently restored to perfect health by the performance of simple and well-recognized operations, of which posterior gastrojejunostomy is the most widely applicable. If it were not for the remote possibility of cancer developing later in the scar of the healed ulcer these cured patients might be considered quite as good risks for insurance as if they had never had a lesion. As it is the recognition of this fact, as well as the growing knowledge that ulcers may be the actual though unsuspected seat of cancerous or precancerous change, has led many leading operators to routinely excise the ulcer at the time the gastrojejunostomy is done. For reasons which are not clear the liability of cancer is much greater in gastric ulcer than in duodenal ulcer.

To sum up the subject of peptic ulcer in its relation to life insurance I may offer the following conclusions: That the history of an acute ulcer in early life, followed by a perfect recovery as shown by unimpaired gastric function, may be ignored.

That any fact or facts pointing to the presence of gastric or duodenal ulcer, active or latent, at the time of examination should absolutely preclude a favorable recommendation.

That a history indicating the existence of a chronic ulcer in the past, in which recovery has apparently taken place and where considerable time has elapsed, should be considered as doubtful. In this connection it should never be forgotten that over 50 per cent. of medically cured cases recur.

That in an operated case the judgment may be favorable if full information of the nature of the lesion and of the operation is obtained, if the patient has been symptomless and shows other evidence of full recovery, and if sufficient time has elapsed, say three years, to insure the permanency of the cure.

That incisional hernias in the upper abdomen are very rare, at least with the American surgeon, and a full half of those that occur are featureless.

In closing I wish to apologize for many omissions pertaining to the subjects I have discussed, and particularly do I regret that the limitations of a short paper have prevented even a mention of such interesting fields as the kidney, the prostate and bladder, the rectum, the female pelvis, visceroptosis, and others.

2117 Pine Street.

## VAPOR ANESTHESIA AND ITS ADVANTAGES.*

By HENRY CHARLES FALK, M.D.,
NEW YORK.
HOUSE SURGEON FRENCH HOSPITAL.

About a year ago the French Hospital acquired a Gwathmey Vapor Apparatus, which has since been used by the internes in all cases, approximately 800. The advantages of this method over the closed and drop methods formerly employed, were so apparent that it soon replaced them as a routine procedure.

The apparatus consists of three bottles placed together, with a single stop-cock. In the first large bottle is placed 4 oz. of ether; in the second, which has a small glass container, 10 oz. of chloroform, and in the third some hot water, to which may be added one or two drachms of the essence of orange, in order to disguise the odor of the ether. The foot-pump which comes with the apparatus, forces the air through the ether, and then through the medicated hot water, heating it and disguising its odor before it reaches the patient. The chloroform is treated the same way. The stop-cock is so arranged that the anesthetics may be given separately or in combination as desired.

Instead of using the open mask which comes with the apparatus, we use a metal one made according to a design kindly loaned us by Dr. Gwathmey. This mask allows the use of the gas-ether-vapor sequence. It also gives us a closed method of anesthesia.

According to our custom, the interne anesthetist makes it a point to see all patients before they come to the operating room, and usually orders ⅛ gr. morphine one hour before the operation, and another ⅛ + 1/150 atropine a half hour before. The quantity of morphine, and of atropine when it is given, varies according to the age, size, and condition of the patient.

The patient in due time is brought to the etherizing room. The gas bag is filled and the mask is placed over the patient's face. Before the gas is turned on, however, warmed air, carrying some of the essence of orange, is pumped into the mask so as to allay the patient's nervousness; then the gas is turned on. When the patient shows signs of beginning unconsciousness, the disguised ether vapor (warmed) is turned on; the quantity being gradually increased until the air carried through the tube is saturated with ether.

Owing to the preliminary medication, the patient comes to the etherizing room in a tranquil state of mind, and takes the anesthetic quietly, the chances of psychic shock being thus lessened.

On turning on the warmed ether vapor, the smothering sensation, coughing, or spasm of the larynx, which patients sometimes experience with cold ether, does not occur. The patients go under easily, and the stage of excitement is almost always absent. The respirations are normal, the pulse is regular, and the color is good. The operation can easily begin in from 5 to 10 minutes after the mask is applied.

For alcoholics, athletes, and in all patients who require larger doses of ether than usual in order to become narcotized, we attach between the gas bag and the face piece the ether chamber from any closed ether apparatus. I have noticed in almost all cases where this arrangement is used that when the cold ether is turned on, however gradually, the patient immediately begins to swallow and show signs of ether irritation, even though previously getting a saturated warmed ether air.

The majority of patients say that the sensations while narcosis is being induced are not as disagreeable as they were led to believe. If they have taken a cold anesthetic on a previous occasion, they usually mention the absence of the disagreeable "smothery" feeling during the induction. In the hands of the experienced anesthetist the patients do not have this feeling, but one-third to one-half of the patients narcotized by the average interne will complain of it. This is eliminated when warmed ether vapor is used.

During the narcosis the patient's pulse and color are nearly normal, the respirations are quiet and regular. The mucous râle and snore are absent.

Another advantage of the Gwathmey vapor apparatus is that the percentage of air and ether can be kept at an even plane and increased or decreased at will. This apparatus allows a more even plane of anesthesia, because in it we have a mechanical device with which we can absolutely regulate the amount, so that the patient gets the same strength vapor with each inspiration and more or less according to necessity. On the other hand with the drop and closed methods, the amount of ether given is regulated by the eye, and is learned only from long experience, vapor strength even then being irregular.

A fact which very soon came to our attention after using the warm ether vapor was that sponges, suction apparatus, and other means for the removal of saliva and mucus from the throat, were unnecessary as the warm ether vapor did not excite the salivary glands to hyperactivity.

We also noticed that there was little or no bronchial irritation. The patients with chronic lung affections did as well with the warmed ether as with cold chloroform. Since this apparatus has been in use, we have narcotized ten patients suffering from pulmonary tuberculosis, and in none of those cases did any post-operative bronchial irritation develop.

In operations on the head and neck the vapor method is far superior to the other methods, as it requires the anesthetist to use less space than with the open cone or closed mask, there being no need of dropping ether on the mask or in the ether chamber. When the patient is under and the mask set, the operative field may be draped without fear of the anesthetist dislodging the towels or unsterilizing the field by his movements.

In operations on the nose and throat, this apparatus, plus the Gwathmey-Ferguson mouth gag, allows the maintenance of an even, continuous narcosis with the anesthetist absolutely out of the way of the operator or his assistants. After an operation for ranula, in which this method was used, the operator remarked that he had had as much comfort and freedom of movement as in any laparotomy.

*Read by invitation before the New York Society of Anesthetists at New York Academy of Medicine on May 15, 1912.

In tonsillectomies, where the operator wishes to work slowly and carefully, the mouth-gag method, plus a suction apparatus for the blood, gives an almost ideal field for operating.

According to animal experimentation, consciousness will return more quickly in a warm room than in a cold one. With this apparatus we are able toward the end of the narcosis to pump into the mask a large amount of warm air. This not only seems to hasten the recovery of consciousness, but also to reduce the post-operative nausea.

The post-operative vomiting is absent in about 60 to seventy per cent. of all cases. We seldom have a case of protracted vomiting. In the six months just passed, no patient has had to have his stomach washed for post-operative vomiting from the anesthetic where the warmed ether vapor was used. In the six months previous to that, when cold ether was used, we had an average of one or two a month.

The post-anesthetic delirium or "ether jag" is absent since using the warm ether vapor with a preliminary hypodermic of morphine. The patients are placed in bed, and instead of tossing about and requiring to be restrained, they rest quietly for from 4 to 5 hours and then awake as if from a natural sleep.

The last fact with regard to the apparatus which I wish to consider is the small amount of ether used to keep the patient narcotized. In a series of 100 cases, 60 per cent. of which were laparotomies, we averaged 2½ to 3 oz. per hour. The excretion of this small amount of ether throws less strain upon the vital organs. With our former methods, 95 per cent. of the patients had post-operative albuminuria, and about 70 per cent. of these had hyaline casts. With warmed ether 30 per cent. of patients showed an albuminuria and only about 3 to 4 per cent. had casts. Of secondary importance is the saving of one half in the expense of the anesthetic, which recommends the apparatus for institutional work.

## THE DIFFERENTIAL DIAGNOSIS OF LOBAR PNEUMONIA.*

By CHARLES EDWARD NAMMACK, M.D., LL.D.,

NEW YORK.

VISITING PHYSICIAN TO BELLEVUE AND TO ST. VINCENT'S HOSPITALS; PROFESSOR OF CLINICAL MEDICINE IN CORNELL UNIVERSITY MEDICAL COLLEGE IN NEW YORK CITY.

When a patient is seized with a sudden chill, followed by chest pain, fever, cough, rusty sputum, herpes facialis, and respirations which are accelerated to a greater proportion than one to each four pulse beats, it hardly needs the corroboration of increased vocal fremitus, dullness on percussion, bronchial breathing with bronchial voice and whisper, to establish the diagnosis of pneumonia. But all cases are not so frank. Any of the classical symptoms or physical signs may be either wanting or misleading. This is due to the fact that pneumonia is not an inflammation of the lungs, but a general pneumococcus infection with the lesion in the lung as but one of the manifestations. Physicians who have been trained to look to the lungs, and to the lungs only, for evidence of pneumonia, will therefore often be in doubt, and will hesitate to announce the diagnosis. Yet the local lesion in the lungs may bear no proportion whatever to the severity of the pneumococcus infection, and, after the crisis has passed, the physical signs may show no change in the lung condition although the patient has come from a condition of extreme hazard into one of safety. The results of bacteriological examinations at autopsy have shown that general pneumococcus infection may even occur without any distinct localization in the lungs.[1]

The three classical stages of pneumonia usually described—engorgement, red hepatization, and gray hepatization—are not similar to any results of inflammation which we observe in other organs than the lung. The stage of engorgement is probably due to a slowing or complete stagnation of the blood current in the capillary vessels, which stagnation results in the escape into the air-cells of leucocytes, red blood corpuscles, desquamated epithelial cells, small strands of fibrin, and a large amount of serum. This stage lasts but a few hours, until the contact of air causes this transudate to coagulate into a solid, firm and airless exudate, and we then have the stage of red hepatization—so-called. These results are plainly mechanical and physical rather than inflammatory, as we ordinarily conceive the meaning of that term. But now begins Nature's effort at repair, shown by the pouring out of polymorphonuclear leucocytes which infiltrate this exudate and inaugurate the warfare which, when successful, results in the removal of the transudated material and the return of the lung tissue to normal. The consolidation of the lung, therefore, which occurs in pneumococcemia, is incidental to the curative process which Nature must set up to rid the organism of its invaders. And it must always be remembered that other bacteria besides the pneumococcus can cause the same leucocytosis and consolidation. It is probable that this process finds its site of election in the air cells of the lungs, because at that point the blood is most likely to undergo coagulation, for the reason that it is here that the blood loses its $CO_2$ and it is known that $CO_2$ has some effect in hindering the formation of fibrin. And as the lower lobes of the lungs are the most active, they are the lobes most frequently affected.[2]

This sketch of the pathology of pneumonia explains why we naturally turn to investigation of the lungs for the evidence on which to base our diagnosis, remembering always that pneumonia is a disease of protein manifestations and that it often presents abnormalities of type. Some points in the clinical history should put us especially on our guard. A good history is half the diagnosis, occasionally the entire diagnosis. During the prevalence of epidemic influenza, which prepares the soil for the microbe of pneumonia, especial care is necessary, as the physical signs may then be delayed until the fourth or fifth day and much harm may be done meanwhile by the use of coal-tar depressants, used for their analgesic effects. These cases of "grip penumonia" are usually cases of unrecognized lobar pneumonia from the beginning, and would show a leucocytosis from the beginning, in contrast with influenza. Of course, pneumonia may follow influenza as a sequel, especially when patients go out too soon, and it is a grave complication when it occurs. Abdominal pain may be a prominent symptom of the stage of invasion, especially in children, but will usually not be associated with rigidity of the abdominal wall. Meningeal symptoms are apt to mislead, and it should always be borne in mind that pneumonia in children looks like cerebral disease. Earache in children with disturbed pulse-respiration ratio should invite attention to the chest.

*Read before the Eastern Medical Society, January 10, 1913.

Convulsions are encountered in children, epileptics, neurotic individuals, drunkards, and the insane. Delirium may arise from various causes: fever, toxemia, inanition, delirium tremens, cyanosis, and meningitis, all occurring as complications of a pneumonia.

Free hemoptysis is very rare as an initial symptom and should always arouse the suspicion of a latent tuberculosis.

| | Pleurisy with Effusion. | Primary Lobar Pneumonia. |
|---|---|---|
| Onset: | Chilliness, persisting for a few days. | Acute, rigor, lasting one hour. |
| Pain: | Sharp, stitch-like, localized. | Acute, similar, but soreness more diffused. |
| Cough: | Frequent and irritating; no expectoration. | Accompanied by rusty or bloody expectoration. |
| Sputum: | Absent. | Shows pneumococcus. |
| Fever: | Moderate, continuous, decline by lysis. | Intense; crisis 5th to 9th day. |
| Prostration: | Moderate. | Marked. |
| Countenance: | Pale and anxious. | Congested; mahogany flush. |
| Herpes: | Does not appear. | Quite common. |
| Thorax: | Marked distention. | None. |
| Fremitus: | Diminished or absent. | Marked. (Absent when bronchus plugged.) |
| Percussion: | Flatness with great resistance. | Dullness, less resistance, sometimes tympany. |
| Neighboring Organs: | Displaced. | No displacement, if uncomplicated. |
| Change in Percussion: | By position, if sac is partly filled. | Absent. |
| Breath sounds: | Diminished or absent. | Increased. |
| Bronchial breathing: | Frequent, but diffused and distant. | Harsh, close to ear, localized. |
| Râles: | Absent as a rule. | Present in 1st and 3d stages, unless bronchus plugged. |
| Vocal resonance: | Diminished or absent. | Bronchophony (loud) unless bronchus plugged. |
| Friction sound: | In early and late stages. | None, except crepitant râles in first stage. |
| Aspiration: | Yields serum. | Yields few drops of thick blood. |

A moderate range of fever is not to be dreaded in pneumonia. Fever usually betokens a specific reaction against injurious materials which affect the tissues, and is, in its essentials, a protective reaction.[3]

The pulse rate is regarded by many as an index of the severity of the infection, and when it exceeds 120 in an adult is of grave concern. But the pulse rhythm, volume, and tension, must also be considered, and a comparison of the pulse rate with the systolic blood pressure as shown by the sphygmomanometer is helpful. When the blood pressure reading does not fall below the pulse rate, the outlook is excellent. The character of the breathing is often absolutely diagnostic. When the respirations are restricted by pain so as not to be sufficiently deep, cyanosis soon develops with distended jugular veins and cold extremities.

| | Primary Lobar Pneumonia. | Acute Tuberculous Pneumonia. |
|---|---|---|
| Onset: | Sudden, with chill and chest pain. | Gradual, with chilly sensations and bronchitis. |
| Sputum: | Viscid, sticky, rusty, contains pneumococcus. | Purulent, copious, blood-tinged, contains tubercle bacillus. |
| Temperature: | Continuous, ends by crisis. | Remittent, intermittent, without crisis. |
| Herpes: | Common. | Less so. |
| Sweating: | Not severe until crisis occurs. | Profuse night sweats. |
| Emaciation: | Not marked. | Well marked. |
| Consolidation: | Followed by resolution. | By cavity formation. |
| Limitation: | To one lobe or lower part of lung. | Extends from apex and affects both lungs. |

| | Lobar Pneumonia. | Bronchopneumonia. |
|---|---|---|
| Age: | Between 3 and 8. | Under 3, chiefly under 2. |
| Previous Health: | Good. | Delicate and debilitated. |
| Bacteria: | Pneumococcus. | Primary, pneumococcus; secondary, streptococcus, but usually mixed infection. |
| Onset: | Sudden, with well marked symptoms. | Gradual, sometimes insidious. |
| Course: | Typical, crisis usually 5th to 8th day. | Not typical, rarely crisis, lasts 3 or 4 weeks. |
| Involvement: | Unilateral, left base most, right apex next. | Bilateral, both lower lobes most frequently. |
| Râles: | Only early and in resolution. Unilateral. | Heard throughout. Bilateral. |
| Consolidation: | 2d or 3d day. Area sharply defined. | 4th to 7th day. Shades off. |
| Resolution: | Rapid, usually complete. | Slow. Often incomplete. May become chronic. |
| Relapses: | Rare. | Frequent. |
| Sequelæ: | None, except empyema. | Empyema, interstitial pneumonia, tuberculosis. |
| Mortality: | 4 per cent. of all cases. | 50 per cent. of primary, 65 per cent. of all cases. |
| Dyspnea: | Less marked. | Marked. |

Albuminuria is found in about one-half the cases. It is usually transient, except in drunkards and those previously afflicted with kidney insufficiency. Splenic enlargement, as in other acute infectious diseases, is often found. The blood furnishes valuable diagnostic, as well as prognostic, information. A moderate leucocytosis is distinctly favorable. A high mortality attends cases with leucopenia. Thus of 108 cases without leucocytosis, 94 were fatal.[4] In diagnosis, the presence of leucocytosis excludes malaria, typhoid fever, uncomplicated influenza, uncomplicated tuberculosis, measles, and non-suppurative parotitis.

In contrast to the usual type of pneumonia, certain clinical varieties are sometimes puzzling. Wandering or migratory pneumonia may affect different small areas at different times, prolonging the course, delaying the evidences of crisis, and making recognition difficult. Senile pneumonia has a very insidious onset, without much fever, with low leucocyte count, with very evident cardiac weakness, and with tendency to failure of resolution ending in fatality or with termination in abscess or gangrene of lung. Apical pneumonia is usually attended with delirium and hyperpyrexia. Central pneumonia, beginning in the deeper parts of the lung, may not show definite physical signs until the process approaches the surface, but will present fever, leucocytosis, and accelerated respiration rate. Postoperative pneumonias are becoming less frequent since greater attention has been paid to skill and care in anesthesia. Lobar pneumonia in childhood often presents a very different clinical picture from that in adults, and yet one so characteristic that the Sisters of Charity in charge of the children's wards at St. Vincent's, and at the Foundling Asylum, often make the correct diagnosis by inspection

alone. The children are listless, "dopy," flushed, feverish, coughing, and the respiration-pulse ratio increases from 1 to 4, to 1 to 3, or even to 1 to 2. You may get dullness or râles later in the disease, but in the beginning you must depend upon sudden onset, fever, prostration, and disturbed respiration-pulse ratio, as indications of the invading toxemia.

Keeping in mind then the various aspects which pneumonia may present, we next invoke the aid of physical signs to elucidate our diagnosis. Mensuration of the chest yields little information of practical value. Inspection may show limitation of the respiratory excursions of the chest and diaphragm with perhaps compensatory excursion of the healthy side and increased action of the accessory muscles of respiration. The results obtained by percussion during the early congestive stage or even throughout the disease in central pneumonias, may leave us much in doubt. Auscultation gives us the most characteristic sign in the early stages, namely, the crepitant râle, and associated with this we have diminished vesicular murmur, which later becomes bronchovesicular and finally broncheal or tubular breathing. But often tubular breathing is absent throughout the attack owing to obstruction of the small bronchi with excessive secretion. In fact, in very many cases of pneumonia in the early stages we must depend for diagnosis upon a circumscribed area of feeble and indistinct breathing compared with the opposite side, crepitant râles, slight increase in intensity and clearness of vocal resonance.[5]

When a careful review of the patient's symptoms is supplemented by these physical signs we are prepared to admit the diagnosis of lobar pneumonia, but must bear in mind the possible complications of that disease. As these are really expressions of the pneumococcus infection, they are very numerous. The limitations of this paper exclude their individual descriptions and allow only of their partial enumeration, as follows: Laryngitis and bronchitis, pleurisy, empyema, pneumothorax, hydropneumothorax, abscess of lung, gangrene of lung, subphrenic abscess, mediastinitis, gastro-intestinal complications—especially tympanites, which should be guarded against early, endocarditis, pericarditis, thrombosis and embolism, albuminuria, nephritis, jaundice, acute hepatitis, meningitis, neuritis, hemiplegia, acute otitis media, acute parotitis, acute arthritis, and finally the coincident occurrence of other infectious diseases. From this list it is evident that the differential diagnosis of lobar pneumonia is by no means an easy task in cases with complications. Even cases apparently typical must not be confounded with other resembling chest conditions, of which the most important is pleurisy with effusion. The differential table, taken from Anders' "Practice," 4th Edition, shows the contrasting points.

The next puzzling condition is acute tuberculous pneumonia, and its differentiation is shown in the second table.[6]

In children bronchopneumonia is recognized by the differential points shown in the third table.[7]

Other lung conditions which may give us trouble are pulmonary congestion, which time will usually resolve; pulmonary infarct, which has hemoptysis as a signal symptom and the presence of thromboses in the extremities or in the periuterine veins, and endocarditis as causative factors; and atelectasis, which is indistinguishable from severe bronchopneumonia in delicate infants. Secondary pneumonias occurring in the course of other diseases are often overlooked, but should be suspected and carefully sought for when the respiration-pulse ratio is disturbed. Unresolved pneumonia should never be accepted as a diagnosis until the exploring needle proves the absence of serofibrinous or purulent pleurisy, always remembering that an interlobar empyema may elude the needle. I have seen the very elect of pediatric specialists deceived by interlobar empyema.

## BLUNDERS MADE BY NATURE.

### THE PART PLAYED BY NATURE IN CAUSING DISEASE OF THE DIGESTIVE AND NERVOUS SYSTEMS.

By AUGUSTUS MAVERICK, M.D.,

San Antonio, Texas.

It is a fact well known among arborists that the bark of many trees grows so tight that the life of the tree is endangered from strangulation. The arborist remedies this by slitting the bark. It has been pointed out how nature could easily overcome this defect by a simple arrangement of the corky layer into narrow vertical strips.[1] Careful study of animal and vegetable life in all its forms will show endless examples of how nature through carelessness brings destruction and death to its progeny. It is not necessary, however, to leave home for examples since our own body is full of them. In this article a few of the more important are mentioned, most of which are well known, but few of which are fully appreciated in the etiology of disease. Beforehand, however, it may be well to point out that the line is not always sharply marked between nature and civilization as the predisposing cause of disease. Thus, an inguinal hernia may be encouraged by the weakness of the abdominal muscles due to the more inactive life of civilization, but the underlying cause is certainly a natural defective spot in the belly wall. None will deny that a corn on the small toe is caused by a tight shoe, but few will recollect that the small toe is by nature a degenerative part and for this reason less resistant to any irritation. Diseases encouraged by our walking on two legs instead of four will certainly be acknowledged by all as due to nature and not ourselves. Accepting the estimate of more conservative anthropologists as to the life of man on earth at 400,000 years,[2] we may certainly claim that to walk upright is our natural posture and not a new fashion now in vogue among man and higher apes.

#### THE DIGESTIVE SYSTEM.

Beginning with the digestive system it may be well to start at the top and work down. The teeth in man are by no means naturally perfect and digestive disorders are often encouraged by this fact, but as natural mischief makers of the mouth the wisdom teeth play the leading rôle. These are useless additions to the mouth and in

spite of their size they are never great chewers; on the other hand the pain they cause in making their début and the trouble they so often produce, including abscess, diffuse suppuration, necrosis of the jaw bone, and even cancer, is common knowledge to us all. About 17 persons out of 100 in our race cheat the dentist by not cutting their upper wisdom teeth; they may well consider themselves lucky.

Passing back from the mouth into the throat we come across two little bodies standing up on either side like little tombstones. The simile is a good one since the tonsils and the grave are closely related. Evidently placed by nature as sentries to guard the throat from the invasion of bacteria taken in the food, they have not only failed in their duty, but they have apparently in many people become centers of attraction for all stray germs. It is only necessary to mention the frequency of tonsillitis and the relation between tonsillitis and diseases such as rheumatism, appendicitis, sepsis, scarlet fever, diphtheria, and nephritis. Very similar to the tonsils are the adenoids so common in younger life. Here we have a natural overgrowth of tissue, of little or no use, which on the one hand plugs the breathing space and causes general ill health and deformity of the chest, and on the other hand predisposes the nose and throat to recurring catarrhal affections, including inflammation of the inner ear and deafness.

The stomach and intestines furnish several good examples of the part played by nature in causing disease. Judging by the length of our intestines we should be expert vegetable eaters, but when we consider the digestive juices we are apparently better off on a meat diet. As a matter of fact we are built to eat both bread and meat and can do neither extra well. When nature gave us over 25 feet of intestines to lead a vegetarian life it certainly never intended that we should eat our potatoes hash brown or our rice à la creole; cooking is purely a product of civilization and without cooking what chance would we have against a raw potato, or a bowl of uncooked rice? The nourishing part of vegetable food is locked up in little walls of cellulose which no digestive ferment of ours can break through and it is only by our cooking and our milling of grain that a vegetable diet is made digestible. Herbivorous animals chew their grain until the grain gives off a self-made ferment, but man would evolve many a friendly laugh from the family cow were he to try grinding and rechewing his oats in imitation of this patient animal. The bacterial metropolis in the lower bowel, of course, breaks up much of the cellulose of raw vegetables, but the food is mostly liberated too late for absorption and we can feel sure that these little offenders are not doing all this through mere kindness to ourselves. The cooking of meat, as we knew, is much less important than of vegetables; overcooked meat in which all the albumen is coagulated is known to be more indigestible than raw meat, but meat underdone has the advantage over the uncooked in that the indigestible fibrous network of the meat is broken down.

Similar in importance to cooking, man's cultivation of vegetable products, which has been going on for untold ages, has done much to make these foods less indigestible. As Campbell of London says,[3] "To-day no existing race of man is capable of subsisting upon the products of the uncultivated vegetable kingdom alone," our vegetables and fruits of to-day represent the "finished products of a cultivation . . . started in the unfathomable past." Our unfortunate relative, the chimpanzee, always picks up rapidly in weight when brought from the wilds and placed on a diet of cooked vegetable food in place of the raw products he is used to.

Metchnikoff, who has probably found more fault with the intestinal tract than any other man, points out[4] the disadvantage of such a long digestive tube —how this encourages the retention of food and its decomposition from putrifying bacteria, whose poisonous by-products sweeping through the blood help to make life short and miserable. He claims that the whole of the large bowel is superfluous and cites an instance of a woman who lived happily thirty years with no large bowel at all. It certainly does seem a nuisance to have to waste so much energy eating and working on a lot of indigestible material only in order to keep the large intestine from becoming constipated, instead of being able to satisfy ourselves on a limited amount of concentrated nourishment; even worms and insects have the advantage over us here.

Although no longer needed by us, the colon has remained as a blessing to many homeless bacteria. The colon bacillus, as we know, is the chief inhabitant. If there is any excuse for starting trouble within the abdomen the colon bacillus is right on the spot ready for action. It attacks the feeble appendix, inflames the peritoneum, rots the gall-bladder, plays havoc with the pancreas, causes catarrh of the bowel, the kidney pelvis, and the bladder, produces sterility in the female and makes motherless many a new born infant; sometimes it passes into newer fields, causing pneumonia, purulent bronchitis, meningitis of general sepsis—and all this because we are forced to carry around in us a charitable institute for unappreciative germs. In a recent article Morris[5] of New York writes that now since we are gaining control over many pathogenic microorganisms the colon bacillus remains as nature's chief means for thinning out the human race. It shall be ourselves and not nature who will thin out the race of the future, for the days of the colon bacillus, as of other germs, are numbered. Although nature tries to reduce the race as a whole it still gives individual members many valuable weapons against infections. This is seen in the antiseptic action of the stomach juices, especially the hydrochloric acid, and in the bacteriocidal effect of the succus entericus together with the mechanical action of mucus and the peristalsis.[6] These means are effective in keeping the stomach and small gut sterile, but do not protect the colon; each single grain of residue in the bowel has been found by different examiners to contain from 1,000,000 to 117,000,000,000 bacteria. Bile was once thought to be a great intestinal antiseptic of nature's, but now we use bile in the laboratory as a bacterial food. The valve between the large and small intestine does a great deal to prevent the bacteria of the colon from passing upwards, but it might be noted here that in 150 autpsies Krause[7] found the ileocaecal valve naturally incompetent in twelve cases.

Under the fanciful delusion that everything which is natural is best, medical authorities once considered the bacteria of the colon as beneficial to the body in that they aided in splitting up food which the digestive ferments could not handle. Now we know that the food they break up is liberated too low in the digestive tract for much absorption to take place and that any benefit derived from this

source is completely overshadowed by the harm done from absorption of the dangerous toxic products they likewise manufacture from the food. Constipated individuals get more of their money's worth from the food they eat, but they have to pay a higher price for it in the end. The view of modern authorities is that the intestinal flora, besides exerting no beneficial action, may be of itself, under certain conditions distinctly dangerous, predisposing to constipation or diarrhea. Indol and other bodies belonging to the heterocydic and aromatic series are elaborated and absorbed in the colon and severely taxed the functions of the body and, therefore, of the liver.[8] That intestinal bacteria are not indispensable to life has been recently well proven in France by Cohendy, who kept young chickens alive and healthy under absolutely sterile conditions.[9] The part played by intestinal autointoxication in the production of arteriosclerosis and old age is familiar to all; following the lead of the director of the Pasteur Institute thousands of us to-day are trying to cultivate a flora of friendly buttermilk germs in our colons to outrun the less desirable inhabitants, in order that we may lead a happier life and a longer one.

The orifice or ampulla of Vater where the pancreatic juice together with the bile enters the intestine is so well made that infection passing up from the intestine must be very unusual. Sometimes the pancreas has a second duct of its own which opens independently into the intestine. This is a wise provision on the part of nature and allows the pancreatic secretion to flow freely when the common duct is plugged by a stone. Nature, however, sometimes does good only half way, for the value of this second duct is handicapped by the fact that its orifice is not nearly so well guarded from contamination of intestinal contents as the ampulla of Vater, thus inviting infection and not infrequently being a cause of pancreatitis.[10]

The frequency of visceroptosis, especially in women, would suggest that the support of the abdominal organs is not as perfect as it might be and is not entirely suitable to the erect posture of man. Acute intestinal obstruction is likewise sometimes encouraged by natural architecture. This is especially so in children when a section of gut telescopes itself and plugs the canal. Although the attachment of the mesentery is very efficient in preventing the intestine from kinking on itself like a garden hose, the occurrence of ileus under what is frequently slight encouragement shows that this arrangement is not perfect.

Finally, in connection with the digestive system, what are we to say about the vermiform appendix, that antique of the salad age which is of use to no one unless to the abdominal surgeon? We certainly have no thanks to give nature for this miniature gut which because of its low vitality and ease of strangulation has become the target for all abdominal infections. The frequency of appendicitis is one of the bywords of our times. That nature still has a warm spot in its heart, however, is shown by the fact that about one out of every four persons has an appendix the canal of which is partially or wholly occluded, making the possibility of appendicitis less frequent or preventing it altogether. Very similar to the appendix is Meckel's diverticulum, a remnant of embryonic life which occasionally arises from the lower part of the small intestine and is predisposed to give trouble.

NERVOUS SYSTEM.

The brain and spinal cord representing as they do the switchboard which controls the whole body mechanism, it is not surprising that nature takes special pains to protect them from trauma and infection. This system of protection for the most part is excellent, but there are a few bad loopholes for which even nature cannot be excused. The roof of the nasal cavity is the most conspicuous example. The interior of the nose as we know is always swarming with germ life taken in with the air. Above, the nasal cavity is separated from the brain by a thin plate of bone which would serve its purpose perfectly had not nature perforated it full of holes like the top of a salt shaker. Through these holes run the short nerves of smell together with little lymph channels. As has long been known there is an intimate connection between the lymphatic vessels of the nasal mucous membrane and the lymph spaces beneath the brain, and these little lymph channels form the connecting link between the two. If there was one large nerve of smell which approached the nasal cavity at a less hazardous point and which did not branch until after it left the interior of the skull acute epidemic infections of the brain and cord would be rare. As it is, every germ of epidemic meningitis and acute infantile paralysis which enters the nose with the air has a short and convenient path to the brain along the nerves of smell. That more people are not attacked during an epidemic of one of these diseases is probably due to laziness on the part of the germ than to any lack of encouragement on the part of nature. The apparatus of smell itself being a degenerative organ (since man no longer depends on the odor of his enemies in order to avoid them), like all degenerative and undernourished parts, forms an ideal approach for invading bacteria. Not only do bacteria from the nose gain entrance to the brain, but bacteria from the brain in an infected individual find their way out again upon the nasal mucosa so that they may be puffed and sneezed into the faces of innocent bystanders. Thus Flexnor in a late communication on poliomyelitis[11] states that experiments so far undertaken are in favor of the mucous membrane of the nose being the site of both ingress and egress of the virus of infantile paralysis. In his Huxley lecture he said in part, "The conclusion is unavoidable that the virus [of poliomyelitis] ascends by the nerves of smell to the brain, multiplies first in and about the olefactory lobes, and in time passes, as I believe, into the cerebrospinal liquid which carries it to all parts of the nervous system."[12]

A second natural weak spot in the protection of the brain is the roof of the middle ear. The Eustachian tube carrying infection from the throat to the inner ear is, as well known, responsible for the frequency of inflammation in this delicate organ. Once the hearing apparatus is filled with pus the brain is in constant danger, for as one writer points out, "The roof of the middle ear is a thin plate of bone no thicker than paper. This is all that separates the middle ear from the temperosphenoidal lobe of the brain. Erosion of this plate of bone results in epidural abscess, brain abscess or meningitis."[13] A third natural blunder which encourages infection is the close relation between the veins of the face and scalp and the venous channels within the skull. A pus infection

of the scalp is always a menace to the brain since the emissary veins which pass inwards from the scalp through the skull are always ready to carry infection to start up a meningitis or brain abscess. The reason a simple boil in the cheek is so dangerous is well known.

The bony walls of the brain and spinal cord save many deaths from injury to these delicate parts, but there is one vulnerable point in the adult which stands out conspicuously. The ease with which the neck is broken has probably attracted the attention of many and has long been used as a convenient method of ridding society of a less desirable element. Passing along the back of the unprotected neck surrounded by the weakest part of the vertebra column lies the most vital spot of the nervous system. The slightest twist or blow here may cause instant death. A slender neck with delicate movable vertebræ may add poise and grace to the human form, but when we are flying through the wind-shield of a motor car or receiving the impetus of a falling ceiling, our future prosperity depends chiefly on what happens to our neck, and like the turtle the less neck we have the better.

Since our brain became sprinkled with the ganglionic cells of higher thought it has become the pride of our anatomy. No matter how inferior we may be to other animals in other respects we can always point to our intellect as something unequaled elsewhere in natural history; it is, therefore, unfortunate that our higher ganglionic cells are not near as sensitive to stimulation and do not retain their impressions near as well as the chemicals on a photographic plate or the wax of a phonographic cylinder. This is responsible for the frequent errors of judgment and the many failings of memory so common among otherwise normal persons. The natural capacity of the intellect also seems to be very limited.

There is certainly an age limit to learning. It also seems that for a person to have special knowledge or talent in one line he must pay for it with the rest of his mentality. A remarkable artist or a great scientist is often as simple as a child in the ordinary affairs of life and any number of normal alienists (if there are any) would readily sign his committal to a home for the feeble minded were he not protected by the label of genius. The natural make-up of such an unfortunate or fortunate individual is certainly more responsible for his one-sidedness than his own self-education, for many of these men make elaborate preparations for all kinds of businesses which turn out complete failures. This one-sidedness of the cerebrum, as a whole, is better illustrated in the development of the centers of speech and writing on only the left side of the brain if the individual is right-handed, and only on the right side if he is left-handed, so that when a blow puts one side out of business the other side is as unprepared to take up its work as it was at birth and must be educated from the beginning. Of course there is some question here as to whether it is our own choosing or nature's that we are not ambidextrous, since persons using both hands equally have their centers of speech and writing equally developed on the two sides of the brain.

The central nervous system like other parts has its rudimentary and degenerating structures whose usefulness is in inverse proportion to the harm they are able to do. Mention may be made of the pineal body, that vestige of a central eye in lizard-like animals, no longer of any use to us but not very rarely the birthplace of brain tumors. It is well known that nature in an effort to shorten our trunk is allowing the lower end of the spine to degenerate; there is a tendency to degeneration of the lower part of the spinal cord leaving only the filum terminale. As Wiederscheim, in his interesting little book, "Der Bau der Menschen,"[14] has pointed out, this natural degeneration of the lower cord would help to explain the frequency of disease in this part, most especially locomotor ataxia.

The nerves which branch throughout the body are often compared with telegraph wire, since they both carry messages to and fro. In making this comparison, however, it is well to remember that the wires made by man carry their messages much faster than the nerves made by nature, and that while a single telegraph wire will carry several messages at once, the nerve trunk must have a separate fiber for each. Telegraph wires do not lie as often as nerves do. Thus it is not rare to see a child with beginning pneumonia or pleurisy who has severe pain far down in the abdomen instead of over the chest, sometimes causing the surgeon to operate for appendicitis. A one-legged unfortunate will often experience pain in his amputated limb for months or years after he and his leg have parted.

Improper arrangement of nerves in the body is not uncommonly the cause of trouble. Mention may be made of the left recurrent laryngeal nerve which, instead of branching off from the vagus in the neck, where it is intended, does not branch until the vagus reaches the chest, when it must retrace its steps all the way back to the larynx again. The pathogenic significance of this is that loss of the voice from paralysis of the left vocal chord is often caused by the pressure on the left recurrent laryngeal nerve of an aortic aneurysm, a distended left heart ventricle, or a tumor of the chest. Those under the delusion that what is natural is best will possibly claim that the reason nature makes the laryngeal nerve run down into the chest and back again is in order that the physician may more readily diagnose a thoracic aneurysm. As much as our telegraphic system excels the nerve service of nature what is this last compared with our ability nowadays to send messages through space without any wires at all?

Of our organs of special sense the eyes are the most important and we value our sight next to our life. We do not expect our eyes to see as far as a telescope, as minutely as a microscope, or as quickly as a camera, but we do demand that our eyes be perfect in structure and this they are not. The natural errors of the eyeball have caused endless gossip among eye men for years, and given many phycicists a chance to rap at nature as an optician. Achromatic aberration, astigmatism or spherical aberration, imperfect transparency of the cornea, crystalline lens, and vitreous humor, and one large and several small blind spots in the retina are the chief faults which have attracted attention. These faults are, of course, a great handicap to our sight, and it is only because we have two eyes instead of one and are constantly changing our glance that we are able to get along as well as we do. Thus if we had only one eye and a fixed glance the large blind spot where the optic nerve enters the retina (as one example) would be constantly shutting off large fields of vision. As Helmholtz said nearly fifty years ago, "The blind spot is so large that it might prevent our seeing eleven full

moons if placed side by side at a distance of only six or seven feet."[15] Helmholtz after summing up the defects of the eye as an optical instrument adds, "Now it is not too much to say that if an optician wanted to sell me an instrument which had all these defects, I should think myself justified in blaming his carelessness in the straightest terms and giving him back his instrument." For an idea of the handicap nature has placed on the progress of man through faulty eyes one has only to glance through the pages of Gould's "Biographic Clinics."[16]

Our hearing apparatus plays its part fairly well, but the frequency of mistaken sounds and false ones condemns this organ as imperfect. The mistake nature made in connecting the delicate inner ear with the germ-laden throat by a tube open to infection has been mentioned. The Eustachian tube itself, of course, is of value, but surely nature did not have to let it open into the throat at such a hazardous point. The canal through which the sound reaches the ear secretes a yellow, sticky substance termed wax, which is placed there to catch foreign particles and uninvited insects. Very frequently nature, in its liberality, causes too excessive secretion of wax, the excess plugging the meatus as a ball and causing deafness. Partial loss of hearing from natural causes, especially as age advances, is quite common. There are a number of changes that could be readily made in and about the ear to increase our hearing. Without going into its complicated inner mechanism mention need only be made of the most conspicuous shortcoming, namely, the outer ear or pinna. Funnel shaped ears are valuable to collect the sound waves, but the value of a small, almost flat, fleshy disc like we possess, except for ornamental purposes, certainly cannot be great. When we place our hand to our ear to catch a sound we are doing what nature should have already done in shaping the pinna. Of course now that our own taste in the matter is fixed we would not readily exchange our ears for those of an ass, no matter how much we may envy the sound-catching quality of this good animal's revolving ear trumpets. We are perfectly willing to sacrifice hearing to favor fashion.

507 BEDELL BUILDING.

# A CELLOIDIN-PARAFFIN METHOD FOR EMBEDDING AND HANDLING TISSUE.

BY H. M. FRANCISCO, M.D.,

NEW YORK.

ASSISTANT IN PATHOLOGY, FORDHAM UNIVERSITY, ASSISTANT VISITING PATHOLOGIST, FORDHAM HOSPITAL, FORMER PATHOLOGIST STATE HOSPITAL, IOWA.

NOTWITHSTANDING the fact that there are apparently sufficient methods now in use, each with its own advantage and disadvantage, I want to offer a new and, in a good many ways, a quite convenient method, a method that is somewhat of a modification and a combination of the two older standard methods of celloidin and paraffin.

I would like to state that I have used this method now over a year with all kinds of tissue, especially nervous tissue, and checked it against the two standard methods for some time with pieces of the same tissue and find no shrinkage or artifacts above what we may expect normally. I do not offer this as universally applicable, but merely as a convenience in many ways which will be appreciated by both small and large laboratories.

1. Fix and harden the select tissue in the usual way, *i.e.* Orth's fluid, 5 days; Glia-Beiz, 7 days, etc.

2. Wash in running water 12-24 hours. I usually wash over night in a good stream of tap water. Then cut your sections in the forms and sizes indicated. I try to keep them about 1½ cm. x ½ cm. thick.

3. Pass the blocks through 50 per cent. alcohol, 3 hours; 70 per cent. alcohol, 3 hours; 90 per cent. alcohol, 3 hours; then 96 per cent. alcohol over night.

4. Absolute alcohol 10-12 hours or during the next day. One can keep this absolute by keeping a layer of anhydrous copper sulphate with a piece of filter paper covering it in the bottom of the bottle or jar used.

5. Absolute alcohol and ether over night.

6. Thin celloidin, 24 to 48 hours, the longer period the better.

7. Thick celloidin, 24 to 72 hours, the longer period the better.

8. Pure chloroform, 6 hours.

9. Xylol, 1 hour.

10. No. 1 xylol-paraffin, over night, 12 hours. This is a half saturated solution of 52°-54° paraffin.

11. No. 2 xylol-paraffin, 12-24 hours. This is a saturated solution at room temperature.

12. Melted 52°-56° C. paraffin for 6 hours in the oven at even temperature at 55° C., not over.

13. Orient face down and block with melted paraffin in paper boats properly labeled, and cool rapidly by floating in ice water.

14. When hard trim down specimen to proper size, record label and sketch shape and size of specimen if necessary. Mount on paraffin holder with warmed spatula, or file away until ready to be cut.

15. Cut sections the desired thickness. I find that they apparently cut and can be handled best at 10 micra with a dry knife, as for paraffin sections. Or if sections are larger they may be cut on a celloidin microtome dry with a slanting knife.

16. Carry cut specimens from the knife into xylol to dissolve out paraffin.

17. Carry over into chloroform, to wash out the xylol. This also helps to remove paraffin and straightens the sections somewhat.

18. Carry over into 80 per cent. alcohol. Here they may remain until needed for use or one can put them into small bottles of 70 per cent. alcohol for preservation or transportation.

19. Carry over into water and straighten out. If one has many sections he can here discard those of no use before staining.

Steps Nos. 16, 17, 18, 19 can be performed with single sections or upward to 100 collectively, using a glass lifter and draining each loopful as carried over.

20. Now stain by the selected method.

I would like to state that for the above method I have found a preparation called "Parowax" to answer all purposes well. In fact I have gotten my best results with it.

In summing up we first find a disadvantage in its apparent somewhat lengthy course of handling, and I may state that after the thick celloidin one can mount and cut a few sections then start the block through the solutions, again beginning with the absolute alcohol and employing about one-third the time allotted to each solution up to the thick celloidin. It does not harm the other specimens to remain in the thick celloidin until this block has caught up with them.

One great advantage over the celloidin method is that these blocks can be stored the same as paraffin. After cutting just cover the cut surface with a thin film of paraffin easily applied with a warmed spatula. The blocks in this condition will keep indefinitely in a cool place and can be cut over and over again. I have some now over a year old and one cannot notice any change in the cut and stained section.

In cutting we have some very great advantages over the regular celloidin method and some over paraffin. The sections are cut perfectly dry, thereby doing away with the alcohol slop so inconvenient with its always present tendency to rust the knife edge and if neglected for a few minutes without their alcohol feed the drying out, shrinking and hardening of the celloidin blocks in which state they may be ruined and lost forever.

Sections up to 1 cm x 1 cm or 2 cm x ½ cm may be cut very readily on a Minot paraffin microtome or on a Leitz freezing microtome. On the rotary Minot paraffin microtome one can readily cut 50 to 100 sections, 5 to 15 micra (although I find 10 micra cut and turn out the best) in 5 minutes, and handle the same number on the Leitz freezing microtome in about 10 minutes, or one can cut from 10 to 20 sections from as many different blocks in 30 minutes. If sections larger than the above mentioned sizes are necessary one can use any good celloidin microtome and with the knife set at the usual angle for cutting celloidin one should be able to cut as well and more rapidly than if he were cutting standard celloidin sections and without the disagreeable alcohol slop being present.

Another thing, these celloidin sections will be smooth and without a wrinkle to try the patience of the one that has to stain and mount them.

In staining I find they take the stains somewhat better than the regular methods; that is, a much clearer picture can be obtained. They may be stained by any method that either celloidin or paraffin will take. If paraffin methods are needed one can run the sections on the slide in the regular way and dissolve out the celloidin first with absolute methyl alcohol, then fix to the slide by heat method as in paraffin, then dissolve out the paraffin. Alcohols to water and stain.

If serial sections are wanted embed only small pieces not over ½ x ½ cm and in trimming down leave a fairly wide edge of paraffin. After cutting, bring upon the slide in the usual way, then fasten by methyl alcohol method dissolve out the paraffin with xylol, wash out xylol with chloroform, then 90 per cent. alcohol, 70 per cent. alcohol, 50 per cent. alcohol, into water, when they are ready for staining.

Now, last but not least, we have a celloidin section cut 10 micra or under with all its well known advantages over paraffin.

## SURGICAL TUBERCULOSIS.*

By L. SEXTON, B.S., M.D.,

NEW ORLEANS, LA.

Usually when we speak of tuberculosis, we naturally associate the disease with the lungs, but there is a surgical side of the disease which is just as interesting to deal with from the surgeon's standpoint as is pulmonary tuberculosis to the internist. In a short article as this must needs be, we shall allude to only a few of the most common forms of surgical tuberculosis amenable to operative treatment and to their differentiation from other diseases.

The tuberculous abscess is one of the most common surgical conditions with which we have to deal. They are sometimes designated as chronic, congestive or cold abscesses; they are devoid of the acute inflammatory process of the ones caused by staphylococci and streptococci. These abscesses are likely to occur wherever the tubercle bacilli may be deposited and are consequently in the lymphatic glands, joints, and bones more than in other portions of the body. They are the result of the breaking down of the tubercles which may be accomplished without either pain or acute inflammatory processes. If these deposits of tubercles happen to be under some dense aponeurotic membrane (as pus moves in the line of least resistance) it may follow these fascial planes and come to the surface on the anterior aspect of the thigh or above or below Poupart's ligament, when it originally started in the lumbar vertebræ, as in psoas abscess. The same source of infection may be the cause of an ischiorectal or perineal fistula.

The treatment of an abscess tract of such far-reaching dimensions has been attempted by opening and washing out the tract with weak solution of tincture of iodine or 1 to 5,000 bichloride of mercury, following the injection of the tract with a bismuth vaseline paste. The great danger in the treatment of such cases by open method is the adding of streptococcus, or stapholycoccus infection, to the tuberculous. When an evacuated tuberculous abscess continues to suppurate and remain open for long periods of time it is because of this mixed infection.

Joints and their membranes are liable to tuberculous infection. The knee is more frequently infected than the other articulations, supposedly on account of so much joint surface being exposed to trauma and the large number of lymphatics and blood vessels in the knee joint. The synovial membrane and osseous structure are involved in about equal proportions. The starting point in the bone variety is usually in the head of the tibia or in the femur and the joint may become ankylosed with the leg in the flexed and externally rotated position.

Tuberculous disease of the joints is secondary to that of the lungs, bowels, or lymph glands in nearly all cases. This metastasis is effected through the

*Read by title before the Surgical Association of Jacksonville, Fla.

blood streams and lymphatic vessels; it is very slow in its process, usually confined to one joint, and quite often seems to follow some injury to the joint. It is just as essential for a patient with tuberculous joint disease to require rest, open air, and forced feeding as it is for those patients suffering from the pulmonary form of the disease.

Tuberculous coxitis has the same pathology as in other joints. It is first noticed in children by their standing on the sound limb in order to rest the other, and in adults by a severe hip lameness the next day after any violent exertion. In its first stages the motion of the joint is very little impaired.

The pain may be referred to the knee joint as the anterior crural and sciatic supply both joints, the limb may appear lengthened. A blow on the heel or on the trochanter causes pain. The limb becomes flexed, abducted, and everted. As the disease progresses the spinal column takes on a lateral curvature of the spine, with convexity toward the diseased hip. Abscess usually opens internal to the great trochanter or passes directly backward into the gluteal region.

The most helpful condition for any tuberculous joint is to be at perfect rest. Friction of the opposed surfaces of the affected bones in walking or movement of any kind aggravates the condition, spreading the tuberculous infection. Nature tries to throw up barriers against the invasion of new territory by the tubercle bacilli, but all her efforts come to naught unless the joints affected are kept at absolute rest, the two ends of diseased bones practically being pulled apart. This is equally true whether the infection is Pott's disease of the vertebral column or hip or knee-joint tuberculosis. The best mechanical means for bringing about this absolute position of rest in Pott's disease is the well applied plaster of paris jacket, which has for its resting point the brim of the pelvis and for its support the back and axillary space. Application of these plaster jackets should only be made when the patient is suspended from a tripod by the axillæ and head so that the vertebræ are relieved of the weight of the body and lower extremities. A double closely fitting knit undershirt should cover the entire surface of the body snugly, all bony prominences should be padded. The first rolls of the plaster dressing should be applied during forced expiration, so as to insure its fitting snugly and supporting the vertebral column as it should. While the bandages are being applied, wood, aluminum, or steel strips may be applied on either side of the spinal column, extending the full length of the plaster jacket. The patient should be kept quiet for a couple of hours after the dressing has been put on, in order that no cracks may occur in the bandage. The bed should be located on the gallery or near an open window in all except the most inclement and coldest weather. The patient should be encouraged to eat the most nourishing food, small in quantity, and often repeated so that the very best chance for recovery can be had.

The hip joint, which is the next most frequently involved in tuberculous infections, is amenable to treatment in the same way as the knee, with a light plaster cast extending far up above the pelvis and down the leg so as to immobilize the knee. In treating the hip joint some form of extension apparatus should be fixed to the foot of the bed and adhesive straps held to the inner and outer side of the thigh by a roller bandage. To these adhesive straps a five to ten-pound weight should be attached at night; the foot of the bed being raised for counterextension.

Operative measures about the hip joint are more serious in their consequences than in other tuberculous joints of the body. The latest recommendation in extensive abscesses and destruction of the joint membranes, where operation is imperative, is to remove all the diseased bone, mop the cavity with carbolic acid, followed by alcohol, or with strong tincture of iodine, pack with iodoform gauze, to be removed within a week or sooner, and allow the wound to heal by granulation. X-raying such joints and fistula as are treated in an institution where it is convenient is recommended, as also minute doses of tuberculin combined with the above mentioned methods.

Tuberculous testicles between the ages of twenty and forty are not very uncommon secondary manifestations of the disease. Trauma to the testicle or epididymitis predisposes to tuberculous infection. Fistulous tracts or tuberculous abscesses commonly follow unless an early castration is done. As the physiological function of the testicle is early destroyed after its involvement in the tuberculous forms, no contraindication exists to castration.

Tuberculosis of the kidney is found in about two per cent. as a secondary manifestation of the disease. In 3,500 autopsies only twenty-four cases were of renal tuberculosis, and these were all of secondary involvements. The disease usually being unilateral suggests nephrectomy, provided climatic and hygienic treatment does no good. Removing the kidney should never be done when there is even a moderate amount of pulmonary involvement.

Tuberculosis of the breast is a very rare disease; the breast seems to be involved secondarily to the lungs through the blood and lymphatic vessels. Cold abscesses of the breast are usually tuberculous in origin, the glands in the axilla enlarge just as they do in carcinoma; the abscess is usually painless, the bacilli are few in number in the pus; in fact, they may not be found. Usually these cold abscesses of the breast are relieved by simply opening, mopping out with alcohol and tincture of iodine, and packing with iodoform gauze; if the disease is extensive throughout the breast, complete amputation should be done if the patient is in moderately good health and there is no serious pulmonary involvement.

The post operative treatment in every tuberculous case should be absolute out of door rest, forced feeding, and if possible change of climate, the same as is practised in first stage cases of pulmonary tuberculosis.

505 Medical Building.

**Multiple Lupus Vulgaris Following Measles.**—J. M. H. MacLeod reports the case of a child who had had measles two years previously, and in the convalescent stages of fever an eruption of reddish-brown spots had appeared, which, when first noticed, were about the size of a split-pea and were situated on both arms. These lesions had gradually grown, until at present they varied in size from a sixpence to a florin. They were confined to the arms, there being nine on one arm and ten on the other. The lesions were of the lupus type only; they had been considerably inflamed by some irritating ointment which had been applied, and several of them had become impetiginized. The child was one of a family of twelve, and there was no history of tuberculosis among them, nor, as far as could be gathered, in the antecedents. A physical examination of the child failed to reveal any other stigmata of tuberculosis. Cases of this kind were by no means uncommon. They suggested the possibility that they were the result of an embolic shower of tubercle bacilli, emanating from some broken-down focus of tuberculosis, such as a mesenteric or bronchial gland, which had reached the cutaneous capillaries and there produced the tuberculous lesions.—*Proceedings of the Royal Society of Medicine.*

## THE ESSENTIAL CAUSE OF PROSTITUTION.

IN the various investigations, conducted from time to time with the end of getting at the root of the social evil, there seems to be for the most part a tendency to overlook the fact that practically all prostitutes are essentially different from normal women. In the limelight of investigations and under the influence of publicity the naturally vain and shallow-minded women who follow this profession as a livelihood are usually made to appear the victims of economic pressure which forces them into such a life in order to prevent their starvation. Practically all students of the subject, who are in reality students, that is, those who have made the subject their life work rather than the hobby of a few days or weeks, are agreed that economic pressure is one of the least of the contributing factors to the evil.

When sifted to its last analysis it will be found that as a rule prostitutes are women who have been arrested in their mental development at or about the age of puberty. All the sexual desires of the adult are present in them but the self-control is that of a child of fourteen or fifteen years. Likewise, the constructive ability is that of early youth rather than of adult life. They are in other words mentally incapable of meeting abnormally hard conditions of life by the putting forth of abnormally hard efforts. Just as there are occasional normal habitual criminals so will there occasionally be encountered mentally normal prostitutes. But this is the exception rather than the rule. Tested by the Binet-Simon method for determining mental efficiency, the inmates of the Bedford Reformatory are being found almost universally to fall below the mental age which should tally with the chronological. This falls in line with the argument furnished by the every-day experience of physicians that women of this class are inherently different from the normal. That economic conditions are among the least of the contributing factors to prostitution is also borne out by reflection upon the evil of prostitution as it exists in rural communities and villages. Here it is well known that almost every rural community has one or more women who hold their virtue at the price of less than a square meal in any ordinary city restaurant. It is with them not a question of making a living at all, because were they inclined to do any kind of honest hard labor they could easily live decently among the farmers and villagers. It is not the lack of work that drives them to the life, but the fact that they are incapable of performing honest labor. The Jukes family, with its abnormally large number of prostitutes, as well as the Kallikak family, whose history has lately been compiled by Goddard of the Vineland Training School for feeble minded, are both notable examples of the intimate relation existing between prostitution and feeble mindedness.

At the risk of being thought somewhat radical and, perhaps, a little iconoclastic, we also venture the assertion that as a rule the men who make a business of patronizing prostitutes are below the average in mental ability. Perhaps most men have been guilty in this respect at some period of their lives, but the normal man with normal ambitions and normal ability (of course, there are exceptions) soon tires of such degrading practices and either becomes continent until marriage or else strives to establish sexual relations upon a basis that is not purely commercial. In both men and women the sexual relations, when put upon a strictly commercial basis, argue a grade of mentality which is below the average. Owing to the essential difference in the sexual instincts of the two sexes, it is, no doubt, not quite so much an index of mental inferiority in the man to patronize prostitutes as it is in the woman to practise prostitution. However, the principle is the same in both cases and the inferiority is one of degree rather than of kind.

We are inclined to the belief that a campaign of education of the young men, which includes not only the inculcation of the principle that continence is compatible with health but also that the practice of frequenting places of prostitution betokens a low grade of mentality, coupled with a eugenistic movement to eliminate the feeble-minded strains from which prostitutes are almost universally recruited, offers the most practical plan of getting rid of the evil. Before this plan of action is condemned offhand as visionary and impossible, it would be well to remember that up to the present moment no plan ever yet devised has succeeded in the abatement of the evil by one jot or tittle. From time immemorial nations have suffered the nuisance without being able to cope successfully with it. If all the old plans have failed, why should we not avail ourselves of the knowledge which the comparatively new science of eugenics has taught us and tackle the problem in the light of the fact that practically all prostitutes are mentally below par?

## CONSULTANTS AND CONSULTATIONS.

THE medical consultation is an ancient institution. Hippocrates spoke slightingly of those physicians who did not seek the advice of their colleagues. He was probably the first to recognize the principles of ethics that should govern consultations. For he said that "doctors should not contend with one another, nor make one another appear ridiculous; for in no case should one physician discountenance another because of the latter's opinion." Still, even in the

early days of medicine there was no unanimity of opinion as to the efficacy of consultations. "Turba medicorum perdidit Cæsarem" is mentioned by Pliny as the alleged epitaph of Hadrian. This sentiment is reflected in many of the gibes flung by modern wits at the consultations of medical men, which are only too frequently regarded by the general public as useless and expensive formalities, even if they do not cover up the errors and shortcomings of the original medical attendant. The importance of the consultation was however fully recognized in many countries as long ago as the middle ages. In cases of serious illness physicians were compelled by statutory enactment to summon their colleagues in consultation. This practice reached its climax in the sixteenth century. It is related of Henry IV of France that when he visited his friend the Marquis d'O who was suffering from a retention of urine, he found the patient surrounded by as many as sixteen physicians.

A great deal has been said and written about the medical consultation. Rules governing it have been written into the ethical codes of the medical profession in various countries. As an example may be cited the eight sections comprising Article III of the Principles of Medical Ethics of the American Medical Association. Careful reading of these paragraphs reveals nothing that would not suggest itself instinctively to any physician of common sense as the proper procedure in the conduct of a consultation.

The ceremonial and ethical aspects of the consultation have tended to distract attention from the most important phase of this medical function, namely, its real utility. Regarded in this manner the value of the consultation may again be studied from three different viewpoints, namely, from that of the physician, from that of the patient, and from that of the patient's friends. While it must be admitted that in many instances the physician requests a consultation chiefly to protect himself from ultimate criticism by dividing the responsibility with another practitioner, the real object of every consultation is to benefit the patient. If the latter is suffering from a serious or obscure ailment, or if there is some doubt as to the proper treatment to pursue, there can be no question as to the advantage of a consultation. There are, however, many consultations which are such only technically. With the growing complexity of modern medicine and its division into specialties, the need of expert opinions and special skill in diagnosis and treatment is frequently manifested, and a number of medical men may be summoned to study different phases of the case. The individual is nowadays subjected to a process of analysis and treatment by many specialists. The analogy is not remote which would compare him to the product of the modern factory which passes through many hands before it is completed.

Apart from these cases, and apart from those whose difficulties may require the deliberations of two or more minds for their solution, one may recall instances in which a consultation is of distinct advantage to the medical attendant. If the case has been one under observation for a long time there may have developed by imperceptible degrees new symptoms or new aspects that escape attention because of their slow and gradual onset. The consultant who sees such a case for the first time gets a sharper and more vivid picture of the entire condition than the one who has studied it for such a long time as to become indifferent or oblivious to some of its important features. On the other hand the consultant because of his brief observation and study of a patient may not estimate the true value or importance of certain symptoms and may actually, as he frequently does, render an incorrect diagnosis. The shortcomings of the consultant in this respect are aptly alluded to by A. Manquat in his "Principles of Therapeutics," as follows: "A consultation may have regrettable consequences when the consultant makes a mistake, when he is incompetent, or when his advice, though wise, is not accepted. A consulting physician, even a learned one, may err, for the sufficient reason that, having seen the patient but once, he cannot know his various reactions as accurately as the attending physician. The latter, at times somewhat humiliated under the circumstances, cannot always make acceptable his well-founded objections: out of two wills, both conscientious and thoughtful, may come a practical error as a consequence of the preponderating part played by the physician whose knowledge of the patient is less thorough. At other times the consulting physician is one of those men who, through their diplomacy, greater than their science, have acquired the undeserved reputation of exceptional excellence. As a matter of course, he considers the confrère as an inferior. He starts by reforming the latter's diagnosis without suspecting that in most cases he is substituting an error for a reality. Next, he proposes a new treatment. In case of recovery, he is credited with the success; in case of failure, his reputation saves him."

The moral of all this is: one should be most careful and circumspect in the selection of a consultant. The physician whose business methods and whose knowledge of human nature have enabled him to build up an extensive practice is not necessarily an efficient consultant. This rôle can be played successfully only by one who has sufficient time for study and reflection, and who abhors the intuitive or the "snap" method of diagnosis. However brilliant the consultant, there can be no question that the attending physician is not relieved of the responsibility of making a thorough study of the case before the consultant is called in. It is useless to expect of the latter a careful opinion unless all the clinical and laboratory evidence is available. Only too frequently is the consultant compelled to suspend his verdict until a blood count, a Widal or a Wassermann reaction, etc., has been made.

There are not a few instances in which many consultants are called in, one after another. This practice is a relic of the older days when consultants held animated discussions like those of a modern jury. The multiplicity of consultants is not always proportionate to the wealth of the patient, but is rather suggestive of the ignorance of the latter's friends, of the weakness of his physician, and of a state of panic among all of them. The latterday custom of summoning a consultant from a con-

siderable distance or from a foreign country is rarely conducive to the welfare of the patient, for it fosters an attitude of neglecting important indications or of keeping one's hands tied until the consultant's arrival.

From the viewpoint of the attending physician the consultation may be of real or imaginary value. It may sometimes, however, be detrimental to the best interests of the patient in tending to divide the responsibility of those who are treating him. Only too frequently is the practitioner prone to throw the responsibility wholly on the shoulders of the consultant, to rest content with the latter's opinion, and to cease giving to the case the additional study which it may require. The division of responsibility may have the same paralyzing effect as the division and consequent dissipation of authority in governmental systems. It is far better for the patient that one mind should devote to the study of his ailment its full energy rather than vouchsafe to the patient a half-hearted interest merely because another practitioner of supposedly greater attainments has been called in. Many consultations cannot but have the effect simply of confusing the original medical attendant. Fanciful suggestions and ingenious theories are not infrequently advanced by consultants for the purpose of displaying their own erudition, and may tend to supplant the sounder and more practical views of the medical attendant, which are abandoned because of the superior eminence or the personality of the consultant. This is a serious danger that should be guarded against, chiefly by the exercise of the power of self-reliance which is an important asset in the make-up of the physician.

## THE KIDNEY AND ECLAMPSIA.

There has been almost a continuous modification of the views of the relation of "pregnancy" kidney to eclampsia ever since the first recognition of Bright's disease. At first eclampsia was held to be invariably the result of nephritis, or, in other words, was synonymous, with uremia, but at the present time many would exclude altogether the possibility of any necessary relationship between the two blood states. When a pregnant woman already has chronic nephritis it almost never determines eclampsia. The dissimilarity of the two conditions is set forth in current textbooks.

But while it is clear that in pregnancy toxemia the involvement of the kidney is, as a rule, merely an unessential symptom, the possibility of a secondary uremia from the renal lesion must not be lost to view. The differentiation of the two states in practice would be very difficult without having recourse to the differential blood and urinary tests and it is quite conceivable that the two blood states do not exclude each other's existence. In some autopsies upon eclamptics not the mere von Leyden kidney, but actual acute nephritis is present of a degree to show that uremia doubtless existed.

At a recent meeting of the Berlin Gynecological Society (*Berliner klinische Wochenschrift*, February 24) Zinsser upheld the most modern teaching that the kidney lesion so often found with eclampsia played no part in the causation of the latter, and formed no prognostic or therapeutic criterion. Time was not always afforded for the elaborate blood and urine tests of uremia. Any retention of water, chlorides, and nitrogen due to the renal lesion need not be regarded as permanent. We now know that edema is no absolute index of renal insufficiency, and that there is no parallel between edema and convulsions.

The discussion of this paper revealed the belief of some of the leading authorities that the renal lesion had a direct influence on the eclamptic convulsions, and that many pregnant women are perfectly well until a primary renal lesion develops. It is certainly a question of moment as to whether a woman is being poisoned by her placental albumin, or retained nitrogen, or both; yet this question does not appear very near its solution.

## The Serodiagnosis of Cancer.

Ever since von Bergmann and Kenthe revealed the presence of complement-deviating substances in the blood serum in a number of pathological conditions, including carcinoma, several investigations have been undertaken with the view of utilizing the phenomenon of deviation of complement in the early diagnosis of cancer. The latest research along this line has been made by E. Leschke, who describes his results in the "Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung," Vol. I, No. 21. His work included two separate investigations. First, into the phenomenon of complement deviation in malignant disease, and second, into the so-called cancer cell reaction. As the result of the first series of experiments it was found that the blood serum of patients suffering from cancer contains in 90.2 per cent. of the cases complement-binding antibodies with reference to antigens obtained from malignant tumors. These antibodies are, however, not specific, for they present in many instances the same reaction with antigens obtained from normal organs, as the pancreas, spleen, and liver. Moreover, in cases of syphilis and of certain other diseases associated with degenerative tissue changes the antilipoid substances that are formed react with the antigens obtained from tumors in many instances by binding the complement. The best results are obtained with carcinoma tissue dissolved in antiformin. With this antigen the blood serum of cancerous patients gave 86.6 per cent. positive reactions while the blood serum of patients suffering from diseases other than cancer gave 7.6 per cent. positive reactions. The conclusion is drawn that while it is impossible to make a serological diagnosis of cancer, nevertheless, when taken in conjunction with the clinical practice, positive serological findings may be an important diagnostic aid, provided the Wassermann reaction is negative and provided there are no evidences of degenerative processes in the body.

## News of the Week.

**City Death Rate.**—For the week ending March 22, the death rate in New York was 16.36 per thousand of population, with a total of 1,685 deaths, as compared with a rate of 15.47 per thousand and a total of 1,534 deaths in the corresponding week of 1912. The increase was largely due to deaths from influenza and pneumonia. For the first twelve

weeks of the year, the death rate was 15.78 per thousand, as against 15.60 for the same period of last year.

**Mountainside Hospital.** — The Homeopathic Medical Society of Montclair, N. J., has contributed $650 to the Mountainside Hospital of that town, in recognition of the opening of the private operating-rooms of the hospital to homeopathic physicians. A "whirlwind campaign" to raise $300,000 for the hospital will be started on April 7.

**State Health Matters.**—The report of the committee appointed by Gov. Sulzer of New York to inquire into the financial conduct and management of the various State departments, was submitted to the Legislature on March 24. As regards health matters, the committee considered the request of the Health Officer of the Port of New York for $2,000,000 for new buildings on Swinburne and Hoffman Islands, but it was deemed unwise that the State should this year expend any money for this purpose. The committee also believed that the Health Officer's department should be run on $46,000 less than was needed last year, and recommended that the fees for the fumigation and inspection of vessels should be increased. In regard to the appropriation of $17,000,000 requested for the State hospitals and charities, the committee says that the State has practically no control over the expenditure of this money, under the old methods, and states that the policy of all State institutions should be directly under its supervision. It recommends that the State build at once one or two institutions for the care of the insane, but it opposes the plan of using the Creedmoor rifle range as a site for an asylum.

**Cholera Death Reported.**—From Watertown, N. Y., comes the report of the death there recently from cholera of an Italian who landed in New York just a week before. The Quarantine officials are inclined to doubt the correctness of the diagnosis in the absence of confirmatory cultures.

**X-Ray Accidents.**—To the already long list of medical men who have suffered from the malign effects of the *x*-rays there must now be added the name of Dr. Charles Lester Leonard, professor of Roentgenology in the Philadelphia Polyclinic and College for Graduates in Medicine, and one of the pioneers in his special field of work. Dr. Leonard some years ago lost several fingers from one hand, later the entire hand was sacrificed, and only recently it was found necessary to remove the forearm so as to check the advancing effects of the *x*-ray burns.

**Hospital Celebration.**—The trustees of the Sheppard and Enoch Pratt Hospital of Towson, Maryland, are preparing to celebrate the sixtieth anniversary of the granting of the charter for the institution. Although the hospital has been receiving patients for only twenty-one years, it was incorporated and the board of trustees named on May 24, 1853, Moses Sheppard, the founder, being the first president. It is expected that the celebration will be held either just before or just after the Congress of American Physicians at Washington.

**Infant Mortality.**—As previously announced, an English-speaking Conference for the Prevention of Infant Mortality will be held in London on August 4 and 5, under the auspices of the British National Association, and immediately before the opening of the International Medical Congress. The tentative programme includes the following: The responsibility of central and local authorities in infant and child hygiene; the administrative control of the milk supply; the necessity for special education in infant hygiene; medical problems in infant nutrition; and antenatal hygiene. Dr. Philip Van Ingen is secretary of the American committee, and will be glad to furnish any information on request. He may be addressed at 125 East 71st Street, New York.

**Lister Memorial Fund.**—For the purpose of raising the funds necessary for a fitting tribute to the memory of the late Lord Lister, a committee has been formed in London, from which an appeal for subscriptions has been issued. It is proposed that the memorial have a threefold character, and that it consist of (1) a medallion portrait of Lord Lister, to be placed in Westminster Abbey; (2) a larger and more conspicuous monument, to be erected in some public place in London; (3) if sufficient funds are obtained, the founding of an International Memorial Fund from which grant in aid of researches or rewards for important contributions to surgical science may be made.

**Gifts to Charities.**—By the will of the late Mr. Jacob M. Worbelovsky of Brooklyn, the Jewish Dispensary Association of that city receives $500, and the Montefiore Home and the Beth Israel Hospital of New York, each $1,000.

By the will of the late Mr. Samuel T. Benner of Philadelphia, a bequest of $5,000 is made to the Methodist Episcopal Hospital of that city for the establishment of a free bed in memory of the testator's sister, Sarah Benner, and a like amount to the Presbyterian Hospital, also of Philadelphia, for the establishment of a free bed in memory of the testator's mother, Mary M. Benner.

Harvard University, Boston, receives a bequest of $50,000, to be added to the Ellen Osborn Proctor Fund for the study of chronic diseases, under the will of the late Abel H. Proctor, the bequest become payable on the death of the testator's mother.

**Death of Dr. Egan.**—We regret to learn of the death, on March 30, of Dr. James A. Egan, for many years the efficient secretary of the Illinois State Board of Health and an earnest worker in the cause of higher medical education and of effective State regulation of medical practice.

**Personals.**—Dr. Hugo Kinner of St. Louis, Mo., a graduate of the University in Berlin in 1863, recently received the golden diploma presented by the University to its students on the fiftieth anniversary of graduation.

Dr. Marion O. Biggs of Bowling Green, Mo., has been appointed superintendent of State Hospital No. 1 at Fulton, Mo., succeeding Dr. George Williams.

**Medical Society Elections.**—Arkansas Medical Society.—The Tenth Councilor District of the Arkansas State Medical Society at its meeting on March 19, elected the following officers: *President*, Dr. John L. Smiley, Siloam Springs; *Vice-President*, Dr. C. F. Perkins, Springdale; *Secretary*, Dr. James A. Fergus, Rogers; *Treasurer*, Dr. William A. Pickens, Bentonville.

St. James Parish (La.) Medical Society.—At the annual meeting held in Convent on March 19, the following officers were elected for the ensuing year: *President*, Dr. J. Louis Deslattes, Paulina; *Secretary-Treasurer*, Dr. Louis A. Gaudin, Convent.

**Obituary Notes.**—Dr. Hugh Angus Stewart, assistant professor of pathology in the College of Physicians and Surgeons, New York, died at the

Willard Parker Hospital from scarlet fever, after a brief illness, on March 29, aged 30 years. Dr. Stewart was born in Blair-Atholl, Scotland, on July 28, 1882, and was graduated from the University of Edinburgh with the degrees of M.B. and Ch.B. in 1904. In 1906 he received the degree of D.P.H. from his alma mater, and in 1907 that of M.D. During 1904-5 he served as resident physician at the Royal Infirmary, Edinburgh, and after a period of study in Munich came to this country in 1907, acting as assistant resident physician at the Johns Hopkins Hospital, Baltimore, for two years. He was then appointed assistant professor of pathological histology in the Johns Hopkins Medical School, and in 1909 became assistant professor of pathology in the College of Physicians and Surgeons, Columbia University. He was a member of the Edinburgh Royal College of Physicians, the Society for Experimental Biology and Medicine, and the New York Pathological Society, being vice-president of the last named at the time of his death. He had made notable contributions to the study of blood pressure and conditions of the heart, and had recently been engaged in experiments on the adrenal bodies in the course of which he had achieved results which promised to be of value in the treatment of Addison's disease. His early death, in the fullness of his life, is a sad loss to the science of medicine.

Dr. Carlton Revere Thomas of Boston, Mass., a graduate of the Boston University School of Medicine in 1901, died in the Massachusetts Homeopathic Hospital on March 8 from injuries received by the explosion of a gasoline tank in his automobile. He was 35 years of age.

Dr. Francis M. McElwee of Macon, Neb., a graduate of the College of Physicians and Surgeons, Keokuk, in 1892, and a member of the Nebraska State and Franklin County Medical Societies, and for thirty years county physician, died at his home after a long and painful illness on March 1.

Dr. Malcolm Toland Sime, formerly of Philadelphia, a graduate of the College of Physicians and Surgeons, New York, in 1895, and at one time assistant surgeon in the National Guard of Pennsylvania, died in New York on March 3, aged 40 years.

Dr. Patrick Frederick Gildea of Colorado Springs, Col., a graduate of the College of Physicians and Surgeons, New York, in 1889, and a member of the American Medical Association, the Colorado State and El Paso County Medical Societies, and the American Laryngological, Rhinological, and Otological Society, died in Coronado, Cal., from tuberculosis on March 6, aged 47 years.

Dr. Eugene J. Carolan of Brooklyn, N. Y., a graduate of Bellevue Hospital Medical College, New York, in 1878, and pathologist to the Bushwick Hospital, died at his home on March 15, aged 50 years.

Dr. Frank Abraham McMahon of Fresno, Cal., a graduate of the University of California, Medical Department, in 1897, and formerly a surgeon in the United States Army, died at his home on March 3, aged 45 years.

Dr. Robert S. Macrum of Sewickley, Pa., a graduate of the University of Pennsylvania, Medical Department, in 1897, and a member of the American Medical Association and the Pennsylvania State and Allegheny County Medical Societies, died at his home on March 3, aged 45 years.

Dr. James Livingston Thompson of Indianapolis, Ind., a graduate of Rush Medical College, Chicago, in 1860, a member of the American Medical Association and the Indiana State and Marion County Medical Societies, and professor emeritus of ophthalmology in the Indiana University School of Medicine, died at his home on March 5, aged 80 years.

Dr. Archibald Ezekiel Isaacs of New York, a graduate of New York University Medical College in 1886, surgeon to the Beth Israel Hospital and honorary secretary of the Board of Managers of that institution, a member of the New York State and County Medical Societies, the New York Academy of Medicine, the Physicians' Association, the Eastern Medical Society, and the Harlem Medical Society, died at his home from pneumonia on March 14, aged 46 years.

Dr. James M. Amis of Topeka, Kan., a graduate of the Kansas Medical College, Topeka, in 1898, and formerly assistant coroner of Topeka, died in Galesburg, Ill., from disease of the kidneys, on March 3, aged 40 years.

Dr. John H. Droge of Brooklyn, N. Y., a graduate of Bellevue Hospital Medical College in 1884, a member of the Brooklyn Medical Society, the Associated Physicians of Long Island, and the German Medical Society, chief laryngologist and otologist to the German Hospital, consulting laryngologist to the Bethany Deaconess Hospital, and visiting laryngologist to St. Mary's Hospital, Jamaica, died at his home on March 15, aged 52 years.

Dr. Clarence Russell Grier of Camden, N. J., a graduate of the Jefferson Medical College, Philadelphia, in 1893, and a member of the New Jersey State and Camden County Medical Societies, died in the Cooper Hospital, Camden, from pneumonia, on March 12, aged 42 years.

Dr. Sylvester Emory Strong of Saratoga Springs, N. Y., a graduate of the New York University Medical College in 1862, and a member of the American Medical Association and the New York State and Saratoga County Medical Societies, died at his home on March 17, aged 75 years.

Dr. Charles Faget of New Orleans, La., a graduate of the Medical Department of the Tulane University of Louisiana in 1876, and an authority on the treatment and control of yellow fever, died at his home from diphtheria on March 8, aged 58 years. Dr. Faget's wife and two children died of the same disease only a short time before.

Dr. James Tucker Cutler of Roxbury, Boston, Mass., a graduate of the Harvard Medical School in 1894, visiting physician to the Cullis Consumptives' Home, Dorchester, and to the Massachusetts Homeopathic Dispensary, Boston, and a member of the Massachusetts Homeopathic Medical Society and the Massachusetts Gynecological and Surgical Society, died at his home from pneumonia on March 15, aged 48 years.

Dr. Lorenzo Waite of Pittsfield, Mass., a graduate of the Berkshire Medical College, Pittsfield, in 1850, died at his home on March 18, aged 84 years.

Dr. Jesse E. Wilson of Rochester, Mich., a graduate of the Castleton Medical College, Castleton, Vt., in 1855, died recently at his home, aged 83 years.

Dr. George S. Adams of Stamford, Conn., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1876, superintendent of the Givens' Sanitarium, Stamford, and formerly

for twenty years superintendent of the Westboro Insane Hospital, Westboro, Mass., died at his home on March 16, aged 65 years.

Dr. John C. Parker of Providence, R. I., a graduate of the Medical School of Maine, Portland, in 1891, and a member of the Rhode Island State and Providence District Medical Societies, died at his home from pneumonia after a brief illness on March 12, aged 48 years.

Dr. Charles M. Knight of Chaplin, Conn., a graduate of the Louisville, Ky., Medical College in 1893, health officer and medical examiner of the town of Chaplin, and a member of the local school board, died at his home from diabetes on March 10, aged 57 years.

Dr. Robert H. Taylor of Griffin, Ga., a graduate of the Atlanta Medical College in 1879, and a member of the Georgia State and Spalding County Medical Societies, died suddenly at the residence of his brother on March 12, aged 55 years.

Dr. David M. Finley of Clinton, Ia., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1885, died at his home on March 10, aged 83 years.

Dr. James N. Powell of Corydon, Ky., a graduate of the Medical Department of the University of Louisville in 1862, died at his home on March 8, aged 74 years.

Dr. Frederick G. Domnitz of Wildwood, N. J., a graduate of the Medical Department of the University of Pennsylvania in 1869, died in Philadelphia on March 9, aged 64 years.

Dr. Thomas D. Rogen of Philadelphia, a graduate of the Jefferson Medical College in 1869, died at his home on March 13, aged 65 years.

Dr. Grant Stanley of Sea Cliff, Long Island, N. Y., a graduate of Cornell University Medical College, New York, in 1904, a member of the New York State and Nassau County Medical Societies, the Society of the Alumni of Seney Hospital, and the Associated Physicians of Long Island, attending physician to the Home for Convalescent Babies, Sea Cliff, and associate physician to the Nassau Hospital, Mineola, died at the Seney Hospital, Brooklyn, from diphtheria, after a brief illness, on March 23, aged 38 years.

Dr. Richard R. Trotter, of Yonkers, N. Y., a graduate of the Boston University School of Medicine in 1877, and a member of the American Institute of Homeopathy, the New York State Homeopathic Medical Society, and the Academy of Pathological Science, and consulting physician to the Yonkers Homeopathic Hospital and Maternity, died at his home after a short illness, on March 28, aged 63 years.

Dr. Harry Raymond Bennett of Bridgeport, Conn., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1897, and assistant physician at the Emergency Hospital, died in St. Vincent's Hospital, Bridgeport, from pneumonia, after a short illness, on March 22, aged 38 years.

Dr. Frank Hamilton Peltier of Hartford, Conn., a graduate of the New York University Medical College in 1887, died suddenly at his home on March 20, aged 48 years.

Dr. A. Richmond of Claremont, Cal., a graduate of the Detroit Medical College in 1872, died recently at his home, aged 68 years.

Dr. Jovite A. Lapointe of Biddeford, Me., a graduate of McGill University, Medical Faculty, Montreal, in 1867, died at his home from paralysis, on March 23, aged 69 years.

## Correspondence.

### THE PHYSICIAN'S SELECTION OF HIS MEDICAL ATTENDANT.

To the Editor of the Medical Record:

Sir:—In the pleasure that comes to a physician from meeting with his colleagues, in the spirit of good cheer that manifests itself among the men in our medical and social gatherings, in the courtesies and interchanges of delightful details which show plainly that basically we have a truly professional demeanor and the right feeling for one another, how sad is the ending of many of us. With every patient that comes under our care, however our opinions and our ideas of therapy may be, we nevertheless give the best that is in us to the patient. In their hour of illness we forget ourselves, and even the demands of our family, and think and work for the patients with only the one end in view—to relieve them of their suffering. To this end we oblige the patients and their relatives and friends, seek help of each other professionally for the benefit of the sick by consultations, and resort to every avenue of assistance at our call. Those not so able readily give way to advice from those who may be considered more able than ourselves.

We stay with a patient through all the physical trials and tribulations, and, as time goes on, accumulate a most advantageous amount of detail in the treatment of each particular one in illness, not only medically, but morally, humanely, and in all that means the highest obligations of our callings as physicians. So we go on, day by day, and year by year, from one to another, and when our experience has passed through years certain practical facts are plain to us all.

With this knowledge from experience, we are finally stricken with illness ourselves, perhaps in our last physical struggle with disease. Usually after being up and about longer than we should be, we take to our beds, often more because of the earnest solicitations of the members of our family than from our own desires. There a considerable proportion of us temporize with different medicants (or perhaps none at all are taken), and often though we have been cognizant for years that certain matters were not normal with us. The disease deepens, and then the wife, mother, or friend becomes alarmed, and suddenly takes the initiative against our desires perhaps and calls upon some medical man to see us. It usually is a personal friend, who feels grateful for the chance to help a sick brother, and although he listens to the wife's reports before he sees us, he is told that she 'phoned for him against our wishes and we do not know he has been sent for. He comes to our bedside. We look up and greet him first with surprise that he is there and then with friendly words, not at all like patients do in their anxiety for assistance. He tries to hold himself down to the medical and surgical aspect of the case, but we are more of a friend than a patient and insist upon considering ourselves as such. He goes away with the thought that he has done the proper thing to respond to help for a sick colleague, but at the same time with an inward feeling that he had not covered the case from a medical standpoint as he would have done for a lay person. The next day he calls again; the case is worse and he does somewhat better from a medical standpoint. After a day or so he learns

that Doctor So and So had called and questioned or examined the patient. He now feels only half a desire from a medical standpoint to call again. But he does, and learns that one or more friends, and a few consultants perhaps, have been there since his last call. The case becomes worse, and in the frenzy caused the family often calls one prominent man in the community after another, feeling that they should all come. Many of them do, and go away after more or less of a perfunctory medical service, which the next man changes. With each one who comes, the wife and the family cling to him for the time being, begging for assistance and advice.

In the meantime, the first, second, third, and so on attendant does not call any more. Finally, the condition settles into a coma and the medical man who happened to be called in that same afternoon continues on during the next few hours until the end—probably more because the family had given up hope of saving the Doctor than for any other reason. Such is the unfolding which I have seen and have learned of happening with some of my friends.

Why is it that we as medical men may be irregularly and poorly handled in our last illness? Simply because we are physicians, have physician's families, so many medical friends, and have not given advice as to what to do when we are ill.

There is a time when a medical man becomes a patient—we should all fully remember this and prepare for it. We should tell our people whom we want to care for us when ill, which medical man and surgeon. These two men should be absolutely in charge of the case, without interference by the family. If these two cannot agree on any point, it is understood they are to select a third which they or the family, or even the patient, may choose. And these should be all that have charge of the case, and even if they agree to more, the first nevertheless should be in absolute charge and all should understand this.

Only in such a plan as this can the sick Doctor be sure of obtaining as good a medical service as he deserves, namely, to have someone in charge guide the course of illness and shoulder the responsibility. As the only alternative to this (and it often is the best one to think of primarily as the proper thing to do for ourselves), we should tell our people in our days of health which hospital we should be taken to when ill. The hospital of choice should be a well-organized institution where perhaps our medical friends can be only visitors and in which we are only a patient to do what any other patient does when properly handled, although we may be under those perhaps who are personally not known to us.

I am satisfied that there have been instances in which medical men are not as well handled medically and surgically in their serious illnesses as they could have been and deserved—not that those who come in contact with them are not willing, but because we have not told our families what to do when sickness befalls us, and because our families and the medical men overrun the case when this had not been done and the matter is entirely left in hands so over-anxious and over-willing that steady direction is not common.

Anthony Bassler, M.D.

126 East Sixteenth Street, New York.

## A STRANGE PROPERTY OF LIVING ANIMAL TISSUE.

To the Editor of the Medical Record:

Sir:—Phenomena such as the one I am about to report are usually regarded with utter skepticism; and that such should be the case can scarcely give rise to surprise, since in the end they are generally shown to depend on subterfuges of one sort or another. But this one has now been under observation for so long a time, succeeds so regularly, and has been so often tested by properly qualified men whose good faith cannot possibly be questioned, that it seems worth bringing before the notice of the medical world at home.

The facts in brief are as follows: There lives in Bordeaux a lady who, during the past ten years, has succeeded, whenever requested to do so, in mummifying flowers, plants, fruit, molluscs, fish, and small birds and mammals, as well as the viscera of larger ones, simply by passing her hands over them without actual contact for a quarter of an hour once or twice a day during a period of time varying from a few days to a few weeks, according to the nature and importance of the object under experimentation; by the same influence the acetic fermentation of wine can be prevented altogether. She has never yet failed to mummify small, organic objects brought to her by the series of men who have interested themselves in her uncanny power, and in many instances control-samples, set aside, have followed the usual laws of putrefaction, whereas those treated underwent this special form of mummification; and, what seems more peculiar still, objects brought to her already partially decomposed finally mummify also, the process of putrefaction being brought to a standstill by the emanations from this lady's hands.

It should at once be mentioned that the person in question is not a medium, that neither she nor any of the physicians who have investigated and reported on the case have anything whatever to gain in the matter, directly or indirectly, and that although she obligingly lends herself to any sort of test or experiment that may be desired of her, she insists on retaining her incognito and is known under the pseudonym of Mme. X. She herself has undergone searching medical examination, and has been pronounced perfectly normal in mind and body. Although now fifty years of age, it was only ten years ago that she awoke quite by chance to the fact that she possessed this strange power, by noticing that some oranges and plants she had handled did not decompose or fall to pieces, but remained indefinitely in a sort of dried-up state. This occurrence aroused comment, and she was next asked by a friend to try her power on a pet bird that had died in its cage. Here, too, she proved successful, and since that time she has proceeded step by step, until there are now in existence hundreds of objects that have been mummified by her, the largest so far being a weazel, which has now remained in that condition for four years. A peculiarity about this mummification process is that these objects retain their natural colors perfectly, as well flowers, plants, as animals, and that the little stems continue to adhere firmly to the larger ones in plants, and the feathers or fur to the animals

During these ten years Mme. X. has been visited and tested by quite a number of investigators, no one of whom, however, had the courage to publish anything about this extraordinary phenomenon, so

afraid were they of the ridicule that might ensue. But finally two scientists of Bordeaux, Dr. Clarac, a leading practitioner who had known Mme. X. for four years and followed her career, and Dr. Llaguet, professor of chemistry at the Faculty of Bordeaux, published a note on the case in the "Annales des Sciences Psychiques" (Paris, Charles Richet, professor of physiology at the Faculty of Medicine, director), whereupon Dr. Geley, member of the Société Universelle d'Etudes Psychiques, was deputed to go down to Bordeaux and conduct a complete investigation on the spot. He remained there two weeks, experimenting on the question in every conceivable manner, and then made his report to the society.*

The articles to be treated were simply laid on a table in a laboratory; Mme. X. then came and passed her hands over them for a few minutes, sometimes turning them over so as to influence both sides—whereupon they were wrapped up in paper and placed under lock and key for safety. A séance of fifteen minutes was held every day, in some cases twice a day—Mme. X. keeping up an ordinary conversation with the bystanders while treating the objects—until the desired result had been obtained. Dr. Geley is of opinion that there are no grounds for entertaining any doubts as to the bona fides of the entire affair; but that as to attempting to account for Mme. X.'s mysterious power—that is quite a different matter. What seems to occur is that of the two parts of normal decomposition, dehydration and putrefactive fermentation, the latter is annulled altogether by the influence of Mme. X.'s hands, so that the former runs its course unimpeded, the animal or plant simply drying up, instead of decomposing.

However profound may be one's incredulity in matters psychical, it would seem as though, from the duration of these experiments (ten years), the absolute disinterestedness of all the parties concerned in them, and the standing of the men who have at last brought them to public notice—this peculiar power of Mme. X. is deserving of attentive consideration.

Cecil Kent Austin, M.D.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

OFFICIAL REPORT ON TUBERCULOSIS—GODLEE'S ORATION ON LISTER—ASSOCIATION FOR PREVENTING CONSUMPTION—PROPOSED SALE OF HOSPITAL—A FRIENDLY SOCIETY'S COMPLAINT AGAINST DOCTORS ON PANEL—ANNIVERSARY OF MEDICAL SOCIETY.

London, March 14, 1913

This week the Departmental Committee on Tuberculosis has issued its final report, a very interesting feature of which concerns the administration of the funds for research obtainable through the Insurance Act. Methods of prevention are also considered, of which there are two classes, by those preventing the bacilli from entering the human system by those preventing persons into whom they have entered from developing active disease. The committee consider it idle to hope for the entire elimination of infection, or that the resistant power of human beings can be (apart from some process of immunization being discovered) so increased that infection may be ignored. To diminish infection its absence from milk and meat must be secured, precautions must be taken by those infected, the powers of resistance of the uninfected increased, the social and economic causes further investigated, the eradication of infected cattle from the country secured, and the special treatment of children carried out. For the last named they urge the importance of early diagnosis and recommend the wide application of the principle of open-air treatment as by open-air schools (day and residential), classes in the open, and institutions dealing with those threatened as well as those actually infected. To link up the several authorities concerned it is held desirable that the school medical officer, the dispensary and tuberculosis officer, and the family attendant should be in touch and the same services, as far as possible, be provided for children as adults. Correlation also is as desirable between the school-clinic, the open-air school, and the sanatorium, while special institutions or at least separate pavilions for children should be provided. For the last purpose it is thought about £200,000 will be needed and if this cannot be obtained under the Finance Act of 1911 additional funds should be provided.

The ultimate eradication of tuberculosis, the committee think, is not incapable of attainment, but the bovine disease is one cause of it in man and must be removed. The powers of local authorities are considered adequate as to meat, but additional measures are recommended as regards milk; existing and fresh regulations must be strictly enforced to diminish the risk of contamination from bovine as well as human sources. Legislation as to milk should be on the widest possible basis, with special powers granted by suitable regulations if required. As to the cattle themselves one case in a herd exposes the healthy to infection and as there are satisfactory tests for tuberculosis in cattle a sound herd living in hygienic surroundings should be tested from time to time, any reacting animal removed, and the premises disinfected. Other means must also be adopted for the eradication of bovine tuberculosis.

Dealing with the powers of resistance in the people attention is directed to insanitary houses and other provocatives of disease. The presence of persons in the advanced stage is a danger frequently increased by ignorance or carelessness. Isolation as far as practicable is desirable and the value of education is great and might be promoted by voluntary committees, health visitors and others working in touch with the Medical Officer of Health as well as by lectures and the circulation of literature on the subject. Disinfection of suspected premises is strongly advocated and stress laid on early diagnosis, which may be promoted by the dispensaries. Compulsory notification of all forms of tuberculosis would be, the committee think, of material assistance, and in adults the non-pulmonary disease might perhaps be dealt with in existing hospitals.

Research was carefully considered by the committee and they welcome the fact that the Insurance Act has made available a sum of money for this purpose—hitherto mainly dependent on voluntary agencies. They observe that the bulk of this money will be applied to research on tuberculosis, though it may be used in connection with any disease affecting insured persons. The inquiries to be carried out are defined as including those of "a clinical, pathological, experimental, statistical, and sociological character." Overlapping should be avoided, researches published, and the work generally coordinated. To accomplish it the committee recommend the establishment of an advisory council and

*. The "Annales" 1912, August and October.

of an executive committee—the council to include representatives from different parts of the kingdom, of the government departments concerned, of the medical, scientific, and trading bodies interested in research, of distinguished scientific persons, of business men of proved ability, with in most cases some experience in public work. From twenty-five to thirty members would suffice. But for the executive there should not be more than five to ten and the majority should be experts. The appointments should be made by government and a system of retiring by rotation every year with eligibility for re-election would suffice to change the personnel, while preserving continuity.

To carry out research the committee would establish a central bureau which would correlate and coordinate all results and cooperate with government statistical and other departments, the statistics being so collected and framed as to be comparable with those relating to mortality. A library and publishing department would be under the central bureau which would be under the immediate control of the executive committee. This body would employ investigators in clinical, pathological, bacteriological, clinical, and other scientific researches. Similar researches could be carried on in institutions (including laboratories and hospital wards) under the immediate control of the executive committee. So, if necessary, independently of any institution, prizes might also be arranged.

In connection with this scheme of research the committee advocate the creation of salaried posts, with pensions for whole-time research workers and the engagement of young talented investigators who otherwise might drift. Further they advise the establishment throughout the country (from funds outside the Insurance Act) of clinical laboratories and the extension to medical men and students of additional facilities for acquiring familiarity with tuberculosis in all aspects, especially in its earlier manifestations.

Sir J. Rickman Godlee delivered the foundation oration at the University College Union, last evening. He gave a graphic account of the advances in surgery resulting from Lister's great work. Antisepticism saved many limbs which formerly had to be amputated and enabled the surgeon to explore and work freely in parts of the body which were inaccessible until after Lister's discovery. But, said Mr. Godlee, his merits as a researcher, an operator, and a teacher, great as they were, each and all were eclipsed by his life work. He had done more than put the coping stone on the work of his predecessors—he had himself built much of the structure. There was now no hospital in the civilized world which did not carry out Lister's doctrines.

The National Association for the Prevention of Consumption, formed in 1898, appealed some weeks ago for a sum of £10,000. It professed to have been started at the suggestion of King Edward and its present patron is King George. Three thousand pounds has been subscribed and the committee seem encouraged but more must be secured if the work already begun is to be kept up. It is mainly educative, carried out by traveling exhibitions consisting of diagrams, models, pictures, etc., illustrating the causes and the preventive measures which can be used. Caravans are fitted up with these exhibits and literature for distribution. Lecturers accompany them and everywhere the exhibition has excited much interest. In Whitechapel it was kept open for seventeen days during which it drew 70,000 people. Throughout the kingdom it is estimated that the attendances have exceeded a million. It is an expensive campaign and the association is in need of additional subscriptions.

The annual court of governors of the Mount Vernon Hospitals for Consumption authorized the committee to sell one. They own two separate institutions but so many subscriptions have been withdrawn on account of the Insurance Act that they reported there seemed no possibility of retrieving the position. They owe their bankers £4,500 and the falling off of income has steadily progressed since the passing of the act. They have been compelled to pledge securities which had been set aside to begin an endowment fund, in order to pay the monthly accounts. Dr. T. W. Tunnicliffe and Dr. A. J. Whiting, members of the medical staff, were anxious for delay, speaking on behalf of all their colleagues, who held that the sale would be a calamity. After discussion, however, the proposal was carried with a few dissentients.

A Friendly Society which dubs itself the Rational has made complaints to the Insurance Commissioners against some of the panel doctors who will only furnish certificates for going on and off the clubs. Some also have filled up the certificates with the word "illness," while the clubs want to know the specific disease as questions of compensation and misconduct may arise beyond the matter of pay during sickness. The commissioners in reply state that the doctor is required to furnish such certificates as must be supplied by the sick person in pursuance of the rules of his society or of the Insurance Committee. Further where a society in accordance with its rules requires the cause of illness to be stated, "it would be the duty of the doctor to give the certificate in the required form." It is added that "the Insurance Committee concerned should be notified of any case where a doctor on the panel has refused to give a certificate which he is required to furnish in accordance with the terms of his agreement."

The Medical Society of London's Annual Dinner took place on the 5th inst., Sir Watson Cheyne, president, in the chair. The toast of the society was proposed by Sir F. Champneys, president of the Royal Society of Medicine, who said the most cordial friendship existed between the two societies and observed that last year most of the papers in the medical had been concerned with surgical subjects. The health of guests and kindred societies were duly honored and responses elicited. Sir R. Godlee in his speech gave an interesting account of the early days of this our oldest medical society—established 140 years ago.

2. **The Registered Midwife; a Necessity.**—E. F. Cody notes that the midwife has been an integral unit of European life for centuries, a functionary, trained, licensed, and supervised by the government. Her income shows that she is an important economic factor. Among the newly arrived population of the United States the midwife is a

fixed agent. She can be taught cleanliness, the conduct of normal labor, and the means of recognizing the onset of complications.

**4. Seasonal Variation in Pulmonary Tuberculosis.**—N. B. Burns states that phthisical patients are apt to lose rapidly in weight and general condition in May, June, and the first two weeks in July, which season constitutes an unfavorable and critical period. Phthisical patients make an extraordinary recovery in weight and general condition in the month of August, which is a surprisingly favorable time of the year. August, September, January, and February are the most propitious months for obtaining successful results in treating pulmonary tuberculosis. Forced feeding in the unfavorable season seems to have availed very little in the limited number of cases studied by the author at North Reading.

**5. Factors in the Production of Arthritis.**—H. W. Marshall believes that the confusing clinical manifestations of gout, and of certain mild intestinal toxemias with arthritic lesions, can be explained satisfactorily only upon the basis that such persons possess unusually non-resistant joints, or that excessive amounts of mildly irritating waste products associated with these conditions circulate in the blood, or that both of these unusual variations in blood and joints simultaneously exist. Proportions between factors instead of independent single values of any one factor determine the development of pathological changes. For example, abnormal concentrations of vascular constituents depend upon the ratio between the rate of absorption and rate of excretion; and again the development of pathological joint changes depends upon the ratio between articular resistances and the degrees of irritation produced by vascular constituents acting upon the joints, rather than upon the absolute quantities of irritants in the blood. The latter may be excessive without giving rise to symptoms if the joints are unusually resistant. Any single factor may have either large or small values independently without upsetting normal healthy relations, provided other factors vary in the same proportion and in the same direction. On the other hand when variations among related factors occur simultaneously in opposite directions, and lead to deviations in the blood from normal healthy proportions, then pathological changes make their appearance as soon as tissue resistances are overcome. Comparatively slight variations combined in this way can produce pathological appearances in some instances.

11. Epidemic Cerebrospinal Meningitis. M. B. Wesson.
12. The Effect of Diplodia Zeæ and Some Other Fungi Upon Some Prosphorous Compounds of Maizie. H. S. Reed.

**7. Surgical Catharsis.**—S. B. Overlock states that so far as the surgeon is concerned the use of cathartics may he divided into two groups: their use in preparation for operation, and their use in securing evacuation after operation. Until within recent years every patient about to be subjected to abdominal section was required to undergo a prolonged and thorough catharsis as a routine practice. At the present time there is less rigorous preoperative catharsis and there is at the same time less of postoperative complications. In cases where the operation is elective and consequently sufficient time can be taken for preparation of the patient, a mild cathartic given three or four days before the date of operation, putting the patient on a diet and leaving but little residue, allowing water freely, and giving an enema every morning to wash out the large intestine, should bring the patient to the operating table in good condition. Added to this, some drug may be given to arrest or modify intestinal fermentation. No one would think for a moment of giving a cathartic if he knew there was present, in a given case, a perforated gastric or duodenal ulcer, a perforated appendix, or an opening in any other part of the alimentary canal. Yet the surgeon is frequently told, when a case comes to operation, that a cathartic has been given, often drastic and in heroic doses. The profession at large has not yet learned that in many instances of localized intestinal lesion, like an inflamed appendix, for instance, "purgation means perforation," resulting complications, and often death of the patient.

**10. Unconscious Impairment of Vision.**—S. E. Pendexter points out that a patient may have practically any error of refraction and to a marked degree without being aware of defective eyesight. He emphasizes the fact that a moderate error of refraction, especially with a close application of the eyes, is the one that patients complain about bitterly, while a serious impairment of vision often gives the patient no discomfort save that he (often unknowingly) is partially blind. It is noted that among 1,000 consecutive patients examined at the New York Throat, Nose, and Lung Hospital, 442, or 44 per cent., disclosed an error of two or more diopters. This class is the one in which patients often complain of no symptoms and are unaware of their defective eyesight. The general practitioner should insist on having the vision of all patients tested whether they complain or not.

**11. Epidemic Cerebrospinal Meningitis.**—M. B. Wesson concludes that the only early constant diagnostic sign in this condition is a relative rigidity of the neck. A clear cerebrospinal fluid indicates a bad prognosis. The degree of temperature is a misleading criterion; treatments should be continued until the spinal fluid is sterile. The method of injection should be by gravity; the amount of fluid withdrawn bears no relation to the size of dose of the serum, which should be determined by: (a) the rate of flow of the serum; (b) the amount of discomfort caused the patient, and (c) the quantity that can be given without using pressure. The serum should be given at least once a day and in severe cases every six hours. Vigorously treated cases, if seen early, have no bad after effects.

**12. Diplodia Zeæ and Pellagra.**—H. S. Reed presents data which show that *Diplodia zeæ* and other fungi grown upon corn meal liberate material amounts of inorganic phosphates. Corn meal infected with diplodia loses in weight, the loss increasing with the age of the culture. Aside from the question of the possible toxicity of any of the inorganic phosphates thus liberated or their possible rôle in the etiology of pellagra, the data show what is interpreted as a marked deterioration in the food value of the maize, due to the degradation of organic phosphorus and other compounds. As the fungi continue to grow they may take up a portion of the inorganic phosphates, possibly to form bodies having toxic properties.

3. **Gastroenterostomy and Gastric and Duodenal Ulcers.**—A. A. Berg concludes that simple gastroenterostomy can influence pyloric or duodenal ulcer only when there is an attendant pyloric spasm. In the absence of the latter all the food passes through the patent pylorus, even though a gastroenterostomy is present and so the ulcerated area is not protected from trauma. The reflux of duodenal contents into the stomach is a natural attendant on gastroenterostomy, and serves to alleviate the distressing symptom of hyperacidity, but it does not favor the healing of the ulcer. Gastroenterostomy will not protect against a recurrence of the ulcer. Barring the question of malignant degeneration of a healed or healing ulcer, excision of an ulcer has no particular merit over a gastroenterostomy toward preventing recurrence or recrudescence. Pylorectomy does protect against recurrence, but it has an attendant higher mortality. Gastroenterostomy with pyloric exclusion favors the healing of the ulcer, and has the same value in preventing recurrence as has pylorectomy, with the great advantage over the latter of a very low mortality.

5. **Copper and Experimental Tuberculosis.**—H. J. Corper, L. M. De Witt, and H. G. Wells note that in a considerable number of experiments with both rabbits and guinea pigs, they have never observed copper compounds to produce any favorable effects on the course of tuberculous infections. The rabbits have been inoculated in one eye, which permits of especially favorable observation of the course of the disease. The guinea pigs have been inoculated subcutaneously. Human tubercle bacilli have been used in all experiments. The copper compounds used included copper sulphate, copper acetate, copper oleate and copper salts of amino acids. These have been administered both by feeding and by intramuscular injections begun at the time of inoculation, or at various intervals thereafter, and, in most experiments, pushed to the maximum dosage compatible with preserving the health of the animal. Analyses of both normal and tuberculous tissues have shown the entrance of the copper into the circulation and its deposition in the tissues including the eyes of the rabbits. The authors' figures have not shown any evidence of a tendency for the copper to accumulate in the tuberculous lesions in greater amounts than in the normal tissues, although apparently the copper does enter tuberculous tissues to some extent.

1. **Surgery of the Thyroid Gland.**—J. Berry states that although goiter is common enough among children it very seldom demands operation at this period of life. His reasons for this view are, first, that nearly all goiters in children, being of the pure parenchymatous variety, commonly yield to medicinal treatment; secondly, that any operation on the thyroid gland of a young child involves a possible interference with nutrition and growth and also an appreciable immediate risk to life. It is rarely, therefore, that mere deformity can justify a thyroid operation in a child. Adenomata, unless actually causing serious symptoms, are also best left alone. Most parenchymatous goiters should, of course, not be treated by operation, but rather by removing, if possible, the cause; or by medicinal means, such as the administration of iodine in some form or other, or of arsenic or thyroid extract. The subjects of parenchymatous goiter often suffer much from constipation, and it is worth mentioning that simple attention to the bowels will often cause shrinkage of the tumor by withdrawing fluid from it. A parenchymatous goiter which does not yield to medicinal treatment and which is growing and causing serious dyspnea generally demands operation. It is especially in young subjects at or after the age of puberty that the danger of suffocation is greatest. Complete removal of the gland is seldom desirable.

5. **Carbuncles and Boils Treated by Large Doses of Dilute Sulphuric Acid.**—J. Reynolds and R. J. Reynolds report the favorable results they have obtained with this method of treatment. This consists in administering internally dilute sulphuric acid B. P. in 20 or 30-minim doses, each dose diluted with 2 ounces of water, every four hours. In the case of carbuncle treated by this drug in large doses (small doses are not of the slightest use), changes are observed to take place in the following order. First, within twenty-four hours the infiltrated area of tissue becomes strictly circumscribed; then the slough is observed to soften; during the next few days pus is freely discharged, and the whole affected area shrinks and healthy granulation tissue forms, filling up the cavity until the part is healed. The cicatrization takes place in a comparatively short time from the commencement of the treatment, the period varying, of course, with the size of the lesion. The only external application is a dressing of carbolized vaseline (1 in 20). Naturally in cases of what would appear to be streptococcic infection, such as those resulting from abrasions, or punctures by bones of high game, or inoculation by decomposing animal matter, the patient showing early symptoms of septicemia, a somewhat different though favorable course obtains; the high temperature is quickly reduced and the pain and swelling and malaise gradually subside, the patient progressing uninterruptedly towards convalescence. Where the lymphatics are inflamed and the glands enlarged and painful these conditions in a few days also disappear.

6. **Tuberculin Treatment of Tuberculosis.**—N. D. Bardswell finds that the addition of tuberculin to sanitorium treatment increases the chances of clearing the sputum of tubercle bacilli by some 16.6 per cent. in the case of patients suffering from early disease, and by some 17 per cent. in the case of patients suffering from the disease in its moderately advanced stages. This is a material gain, the significance of which is emphasized by the excellent after-history records of the patients who in past years lost their bacilli as the result of treatment. It may reasonably be anticipated that this increase in the number of patients who are now losing their bacilli will be associated with a corresponding improvement in the after-history returns of a few years hence. The preparations of tuberculin which have as yet been used most frequently are Koch's Albumose-free Tuberculin (A.F) and Koch's Bacillary Emulsion (B.E). Koch's Old Tuberculin (T.A.) and New Tuberculin (T.R.) have been used in a few cases. The initial dosage given in the majority of cases was 0.0001 c.c. or 0.00001 c.c, the dose varying with the condition of the patient and the nature of the lesion. The dose was increased when the last dose given produced no marked general or focal reaction;

otherwise the last dose was repeated until it no longer gave rise to such reaction. In increasing the doses the scheme generally followed was to give 0.1, 0.15, 0.2, 0.3, 0.5, 0.7 c.c. of each of the various dilutions of tuberculin used. The maximum dose given was 1 c.c. of undiluted tuberculin. When the higher dilutions are used an interval of two days between the doses was the general rule. With the lower dilutions and the pure preparations the interval was increased to seven days or more. The general condition of the patient and the nature and extent of the pulmonary disease are factors which have to be taken into consideration in determining the dose interval; in some cases, for example, the interval has to be increased on account of the occurrence of a reaction. Reactions are, as far as possible, avoided.

4. Surgical Point of View. W. Arbuthnot Lane.
5. Death by Electric Currents and by Lightning. A. J. Jex-Blake.
6. The Necessity of Recognizing Midwifery as a Branch of Surgery. V. Bonney.

1. **Alimentary Toxemia.**—W. Hale White notes that the simplest type of this condition is that due to pyorrhea alveolaris. This most common type is that due to the presence of certain bacteria. Herter taught that there are probably three groups of cases: (*a*) The indolic, in which the probable fault is that the colon bacillus invades the lower part of the small intestine, and the patient is unable to digest carbohydrates, and usually passes an abundance of indican. (*b*) The saccharobutyric, in which the organism mostly concerned is the *B. aerogenes capsulatus;* the abnormal changes here occur in the large intestine. (*c*) A group combined of *a* and *b*. One must, when thinking of alimentary toxemia, bear in mind that the culture medium itself is as important as the bacteria, and therefore alterations of diet may influence the production of intestinal poisons as completely as bacteria themselves. A good instance of this is the improvement that follows the withdrawal of carbohydrates in cases of carbohydrate dyspepsia. It is possible that sometimes alimentary toxemia may be a hepatic disease, in which substances absorbed from the intestine in all human beings are so altered in the liver of some that they become poisonous, or abnormal bodies arriving at the liver may so alter it that it produces poisons. Anyhow, there is strong evidence that an important function of the liver is to protect one from poisons absorbed from the intestines, and that its efficient performance of this function depends upon carbohydrates. Intestinal toxemia may be caused by intestinal stasis. This is the condition in which such good results have been obtained by Arbuthnot Lane in short-circuiting the ileum.

2. **Bacteriology of the Alimentary Canal.**—F. W. Andrewes lays down the following propositions: (1) In an important group of cases of alimentary toxemia the poisoning is by foreign proteins, as such, the defect lying in the liver, which ought to shield the body from their effects. With this bacteria have, as a rule, nothing to do. (2) The main effect of bacterial activity in the production of alimentary toxemia lies in their ability to carry out protein cleavages beyond the capacity of the ordinary digestive ferments, with the formation of products which, when in excess, the body is unable to neutralize. (3) There is at present little evidence that true toxins, derived from the ordinary flora of the gut, soluble or intracellular, play much part in alimentary toxemia.

3. **Symptoms and Treatment of Alimentary Toxemia.**—R. Saundby reaches the following conclusions: Under physiological conditions the natural protective agencies in the alimentary system are sufficient to shield the body from the dangers of poisons formed therein or of those introduced with the food, provided that these are not in overwhelming amount. (2) Infrequent or incomplete evacuation of the colon is not in itself a cause of disease. (3) Such morbid symptoms as arise result from a breakdown in the protective machinery, in consequence of functional defects or pathological changes in the organs concerned. (4) Wholesome food in reasonable quantities may consist of animal or vegetable protein, carbohydrates, and fat in due proportion, and the evidence does not justify the entire exclusion of animal protein, as being directly or indirectly the cause of toxemia. (5) When toxemia is present treatment should be based on the principles of eliminating the poison already present, preventing any further introduction, and reinforcing the natural protective agencies. (6) Where there is extensive disease of the wall of the colon the exclusion or removal of this organ is a justifiable proceeding after a reasonable trial has been given to medical methods.

6. **Midwifery as a Branch of Surgery.**—V. Bonney notes that as a result of the affiliation of midwifery to medicine in the past, the analogy between reproduction and other natural processes has been too much insisted on. Childbearing is a physiological process, but it stands alone among physiological processes, in that while the rest of them are exercised for the good of the individual, reproduction is exercised for the benefit of the race at the cost of the individual. The toll reproduction exacts from womankind is very definite and is levied on civilized and aboriginal alike; animals, whether domesticated or wild, do not escape it. At no other time in the life of a healthy woman is ill health so imminent as during the period of childbearing. Pregnancy is normally associated with altered metabolic processes, closely verging on autointoxication; labor is an example of nature's rough surgery, puerpery a time of healing of self-inflicted wounds. Midwifery is an almost purely surgical art. Therapeutic treatment finds less place in it than perhaps any other department of our profession. The means it employs are almost entirely mechanical. Its operations, as compared with those of other branches of surgery, are to the full as difficult, and require, from the circumstances under which they are usually carried out, a far greater average degree of care, skill, and fortitude. Further, the liability for infection to follow them is much greater because asepsis of the operation area is much less under the control of the operator. Attendance on the puerperium resolves itself into the care and treatment of wounds of the genital canal—wounds naturally produced, indeed, but of the character of lacerations or abrasions, often associated with much bruising, and situated, as regards the placental site, in a position unfavorable for drainage, and as regards perineal tears in one impossible to render aseptic. It follows, therefore, that the obstetrician stands more in need of modern surgical surroundings, accessories, and assistance than any other class of surgeon if he is to carry out his work in keeping with the present-day standards of aseptic surgery.

**Non-operative Treatment of Cancer.**—Werner, of Heidelberg, gives an outline of the history of this subject. Up to twenty years ago he knew of no remedies save the mechanical and chemical ones. To-day we have in addition radio-, immuno-, toxin-, enzymo-, organo-, and chemotherapy. This greatly increased armamentarium, however, has added but little to the certainty of cure, and one is still in the experimental stage. Nearly all non-operative remedies have a common property. They are cytotoxic and seek to attack and destroy the individual

tumor cell, hence they are very largely toxic in nature; *i.e.* they are cell poisons and not specifics in the strict sense. The oldest and most practicable is Coley's fluid which, however, has no power over epithelial tumors, but only sarcomata. In this connection one may mention rattlesnake venom and bee poison, which attack tumor cells vigorously but are not yet suited to routine use. Several plant poisons (physostigma, etc.) behave in a similar manner. Various hormones and organ extracts have produced good results in experimental cancer. We do not know whether these are attributable to an ordinary toxic action or an immunization. The anemizing action of adrenalin is due, of course, to action on the blood vessels and is not anticytic. Active immunization with tumor material has been tested extensively in animals but not yet in man, for obvious reasons. Ferments have been used off and on for many years. Pancreatin sometimes causes improvement of the general conditions when given by the mouth, and small nodules have been dissolved *in situ* by trypsin injections. The proteolytic liver enzyme has a similar local action, but appears to affect unfavorably the general condition. Glycolytic enzymes may have some positive action, but only, perhaps, as anticytic poisons. Odiers' extensive claims have not been corroborated. Chemotherapy includes also the action of arsenic-holding substances on epithelial growths, local and constitutional. Atoxyl, were it not for its destructive action on the optic nerve, ought to be of value in sarcomatous growths by reason of its selective action for trypanosomes. Salvarsan and the cacodylates have a positive action, but perhaps only as arsenic salts in general, improving the general nutrition. Colloid metals and choline have been on trial for some time. In summing up, it is conceded that none of the preceding substances are to be compared in their results with *x*-rays, radium, and thorium.

**An Ancient Epidemic of Influenza.**—Mittwoch, without making an attempt to trace the entire history of influenza, gives an extended account of an epidemic described by Hamza, an Arabian historian, in the ninth century, A.D. One pestilence began in the Arabian desert in 871 A.D., and reached the Mesopotamian area. In Bagdad its ravages were such that the deaths amounted to five hundred or six hundred daily. But unfortunately we have no clinical details of this episode and hence doubt must remain as to its nature. Sixteen years earlier, however, this interval corresponding to the usually accredited chronological sequence of epidemics of influenza, the same area had been visited by a similar plague, details of which have been recorded. The episode was connected with a cold wave from the North, and the symptoms were essentially catarrhal. The spread of the disease was ascribed to the wind, as has ever been the case until its contagious nature was recognized. There is a sentence which appears to liken the disease to the epizootic in horses. Mortality, while high, was much lower than that of the great folk scourges. Hamza himself nowhere uses the general word pest. The most convincing evidence seems to lie in the chart given by the author from Hamza's description, in which the disease is seen to pursue two different routes, involving respectively the populous Mesopotamian area and the main travel road through Persia.

*March 4 and 11, 1913.*

**Orthotic Albuminuria and Tuberculosis.**—Arnold concludes that the presence of orthotic albuminuria as evidence of incipient tuberculosis in the sense of Lüdke and Stern is only conditionally utilizable. Other general infections such as syphilis must first be excluded. It is also probable that other conditions with subacute or chronic course may give the same phenomenon. In any case the author's own experience does not show that orthotic albuminuria is in any sense characteristic of tuberculosis alone, as claimed by Tanago and Pedraja. He believes rather that it is a sign of either a chronic infection or intoxication. Pollitzer, approaching the subject from another viewpoint reaches the same conclusion.

**Specificity of Protective Enzymes.**—Abderhalden gives the present status of this subject: Have we succeeded in differentiating between the normal nongravida and normal gravida in respect to the behavior of blood serum toward placental tissue? This question must be answered affirmatively by reason of the researches of the author and other investigators. Another question then obtrudes itself, viz., how do nongravida behave who are in some pathologic condition? The author had already found deviations in gravida with pregnancy kidney, and salpingitis. He was next able to differentiate sharply twenty cases of cancer from pregnancy, and likewise cases of adnexa tumors of all kinds. The second question can be decided only by clinicians. In the interest of this research it is of the greatest importance that the investigations shall be so ordered as to lead to no ambiguous finds. Every communication of results which does not answer this requirement will lead to false routes. The difficulty of obtaining the buiret reaction furnishes much opportunity for erroneous interpretation, and alien matter may gain admission to the best fluids from a variety of sources. With the introduction of the latest procedure (ninhydrin reaction) the method of dialysis is placed on a practicable basis but at the same time the danger of errors is considerably augmented.

**Prophylactic Serotherapy of Tetanus.**—Kolb and Laubenheimer have come to some practical conclusions as a result of the study of a special case reinforced by a similar one from the literature; in a severe wound in which gas formation was noticeable, the exciters of the gas phlegmon were demonstrated. Further, there were found in the secretion of the wound tetanus bacilli, without the subsequent development of tetanus. Tetanus antitoxin had been injected into this patient immediately after the injury which suggests the question as to whether failure of tetanus to develop was due to the prophylactic action of the serum. The authors are naturally inclined to a belief in the agency of the latter because the wound was severely infected. At the same time they admit the possibility of another rationale. We know that various pathogenic germs can be present in wounds without determining general infection, and this of course could also hold good for tetanus. It can only be claimed that the injury was typical of the sort which produce tetanus, having the necessary bacterial flora with special emphasis on the presence of the anerobic gas producing germ.

**Two Cases of Severe Lead Poisoning in the Brass Industry.**—Althoff relates this unusual episode which could only have been brought about through years of inhalation of minute quantities of lead present wholly as an impurity. The first patient showed plumbism after fourteen consecutive years of exposure as a polisher of brass articles. The earliest symptoms were gripes in the upper abdominal region, which soon developed into almost unbearable colic, vomiting, headache, and impervious bowels. Some of the supposedly characteristic symptoms of plumbism did not develop and patient insisted that did not have to do in any way with lead. He was treated symptomatically and after five days all evidences of stoppage had disappeared. His recovery was relative, anemia persisting. The other patient was a brother and co-laborer who developed much the same clinical picture after fifteen years' exposure, but in addition symptoms pointing directly to metal poisoning (green line on gums). The greenish perspiration also suggested brass. Symptomatic

treatment caused an involution of the bowel symptoms. The apparent impossibility of lead poisoning led at first to a diagnosis of ileus, which was later changed to brass poisoning. It was subsequently learned that on technical grounds one per cent. of lead is often added to brass. The dust formed in polishing by machinery with emery contains both the latter and brass particles in equal parts. This when inhaled contains not over one-half of one per cent of lead. As already stated, the poisoning is in a marked degree cumulative in character.

**Extirpation of a Large Meningeal Tumor with Local Anesthesia.**—Andree relates a case of this intervention in great detail, the interest centering largely on the anesthetic element, and further, on the great size of the mass, equal to that of a small fist. The recovery was relative, the patient being left with hemiplegic symptoms. The operation was done in two stages, the first of which had to with the cranial opening. This seems an advantage because when ready for the second stage the surgeon finds the limits of the tumor much more sharply defined. In both stages circular local infiltration anesthesia with novocain was practised. The dura was found to be anesthetic; a debatable point, for while Bier holds that the novocain is absorbed directly within the cranium, Krause believes the dura to be naturally analgesic. At present one lacks information as to the extent to which local anesthesia is being used in these cases.

**Chloroform Narcosis and Liver Disease.**—Hildebrandt considers the problem of the role of chloroform in the genesis of hepatic affections. One of the latter alleged to exist is spoken of as delayed chloroform poisoning. There seems no good reason to doubt that if the liver is already diseased, chloroform constitutes something of a menace. Animal experiment shows that the drug can directly set up hepatic degeneration. In clinical medicine it is recognized that when some disease of septic nature, which tends to produce parenchymatous hepatitis, is complicated by the need of a chloroform narcosis, two dangerous factors may act in concert in the production of hepatic necroses. It is advised that before every chloroform narcosis the liver be carefully tested as to integrity and functional capacity. Urobilinuria would contraindicate chloroform, and is furthermore accepted as the chief criterion of the existence of chloroform necroses of the liver. With any suspicion of hepatic lesion one should use ether or some form of local anesthesia.

---

### Deutsche medizinische Wochenschrift.

*March 6, 1913.*

**Cure (?) of Addison's Disease.**—Teschomacher reports a case of apparent cure of this disease for what it is worth. Patient was a woman of 54, whose appearance had undergone a remarkable change within a short time. Ill health had begun with severe migrainous attacks, followed by anorexia and dyspeptic symptoms, slowing up of all movements, prostration, emaciation, etc., and the usual pigment anomalies. Physical examination showed no evidence of organic disease. The blood pressure was very low (90-100). Symptomatic treatment was used at first with slight improvement, and later adrenalin and an arsenical mineral water were prescribed. The symptoms became progressively worse, and the diagnosis, somewhat in doubt because the pigment changes seemed to have come to a standstill, became assured when the latter again became very active. The adrenalin-arsenic treatment, which had not been kept up, and perhaps not even begun (the history is not clear on this point), was now instituted in earnest, but for months no favorable change was noted. Finally, the causation being obscure, the patient was seen to be slowly gaining, and within a relatively short time had almost wholly recovered. The blood pressure was now normal. The migrainous attacks, which had disappeared during the period of low blood pressure, now returned; otherwise the woman was in perfect health. The author says little of the details or effects of treatment, and seems to leave the question open as to whether recovery was due wholly to the remedies.

**Latent Erysipelas.**—Since this term was recently introduced into medical literature by Schlesinger to characterize certain cases of erysipelas, other authors have accepted it in reporting similar cases. Semenow-Blumenfeld reports two of these, of which one may be abstracted to indicate the applicability of the word latent. A woman aged 24 had an immense phlegmon in the submaxillary region, the result of a carious tooth. Over 600 c.c. of putrid pus were extracted from it. The general condition at once became normal, and the cavity began to close promptly. Two weeks later a hard infiltration was felt *in situ*, with slight temperature rise. The nearly healed wound was deepened but no pus found. Despite the fever there were no unfavorable symptoms in wound or discharge. About three weeks after the original incision an erysipelatous blush was seen at the edges of the wound. As this increased the infiltration subsided. The erysipelas migrated on the surface to some extent, eventually disappearing. As the wound had been treated with the strictest aseptic precautions the author is forced to conclude that the erysipelas cocci had been slumbering in the depths of the tissues until activated by the dental trouble.

**Tuberculous Infection in Childhood.**—De Besche as a result of a study of fifty non-selected cases found human bacilli responsible in forty-five, bovine bacilli in three, while in the other two the result was in doubt. Hence, at least in the city of Christiania, from six to eight per cent. of children receive the disease from the cow. The bacilli were all taken from autopsy material, but this does not mean that death was due necessarily to tuberculosis. This was true beyond doubt in twenty-eight children, and in fourteen death may have been due to other causes in part, but at least the children died with active tuberculosis. In the balance, the children did not have active tuberculosis and the bacilli found in their lymphnodes were in a latent state. In each of the fifty cases which De Besche studied, the germs were cultivated, and the diagnosis was assured further by inoculation tests on guinea pigs.

---

**Pneumonic Lesions and Non-Virulent Pneumococci.**—M. Wollstein and S. J. Meltzer state that the intrabronchial insufflation of a non-virulent pneumococcus causes, like the insufflation of a virulent pneumococcus, the development of an exudate in the lungs which, in general, leaves the framework unaffected, and the lesion presents the gross appearance of a lobar pneumonia. It differs, however, materially from the pneumonia produced by virulent pneumococci in the important points that the consolidation tends to a more rapid resolution, the disease is non-fatal, the blood is not invaded by the organism, and the exudate is strikingly poor in fibrin. As to the question which was the starting point for this investigation, namely, whether the pneumonic lesion produced by the streptococcus is merely a form of pneumonia caused by a less virulent organism, it may be answered for the dog, it seems, in the negative. The leucocytic infiltration of the framework of the lungs which occurs invariably in streptococcus pneumonia, and which is practically absent in the lesions caused by the virulent as well as by the non-virulent pneumococcus, is a strong enough feature to form a dividing line between the two forms of experimental pneumonia previously described.—*Journal of Experimental Medicine.*

## Insurance Medicine.

**Albuminuria, Pathological and Physiological, with Reference to Life Assurance.**—A. E. Finckh of Sydney, in a paper read before the New South Wales Branch of the British Medical Association, says that in cases of apparently healthy individuals who show albumin in the urine, we are in the habit of safeguarding ourselves by the use of such terms as physiological albuminuria, functional albuminuria, and transitory albuminuria. By using one or other of the above terms we intend to indicate that, although albumin is present, there is no definite pathological derangement, and therefore the condition of the individual is not necessarily a grave one. The question thus arises as to the exact meaning of the above terms, and the advisability of employing them. The term physiological albuminuria is evidently based upon the fact that so many text books mention that a minute quantity of albumin is normally present in urine. When we consider that protein of any sort can be found in normal urine only to the extent of about .002 per cent., an amount so small that our usual laboratory methods do not even detect it, we must, for all practical purposes, consider that normal urine does not contain even a trace of albumin. He thinks therefore that it would be better to discard the term physiological albuminuria altogether in this connection.

The term functional albuminuria is perhaps a better one, but also has its objections. In medicine the word functional is usually employed as opposed to organic; it is used to indicate that the sign or symptom to which it is applied is not due to any organic lesion. When dealing with urine, the above meaning of the word brings us at once into difficulties, for even in so grave a condition as granular contracted kidney, where the pathological changes are pronounced, it is possible to find a total absence of albumin. Therefore, one must be guarded in employing this term. The third term, transitory or transient albuminuria, seems to be the only one that should be employed in insurance work. It means nothing beyond the fact that the urine occasionally contains albumin, and it is left entirely to the clinician to put the proper construction upon such finding.

Albuminuria should always be looked upon as pathological; its causation is due to some abnormal condition of some organ or some system. It should not be forgotten that the albumin found in a urine may possibly be due to the presence therein of blood or pus of purely urethral origin, or of vaginal or prostatic secretions. Also albuminuria in any febrile condition, as typhoid fever or pneumonia, would not be taken into account when concerned with life insurance work.

When the amount of albumin in a urine is comparatively large, there is no difficulty in detecting it, but when the amount is small, perhaps minute, one does not always feel confident as to the reliability of the ordinary methods of testing. The two methods that may be easily employed in one's daily work, and yet are of an exactness which meets the requirements of large chemical pathological laboratories, are the old established test of boiling and Heller's test.

Exactness must be employed in the performance of these tests. Thus in the boiling test the urine must be first rendered perfectly clear by filtering. Urine containing bacteria will not filter clear, as the organisms pass through the ordinary filter, but in such cases examination would be deferred. The urine must be only faintly acid. If necessary a 25 per cent. dilution of nitric acid must be added. If the urine is very acid it should be diluted with a saturated solution of sodium chloride. Acetic acid must not be used on account of the possible formation of acid albumin which is not precipitated by boiling. Take 10 c.c. of such clear acid urine and boil; after boiling add 10 or 20 drops of 25 per cent. nitric acid, or two or three drops of 25 per cent. acetic acid. Do not boil again, since in the case of nitric acid having been added, partial solution of the albumin will occur. The precipitate must appear at once on boiling otherwise it is not albumin. Nitric acid should be preferred, as even a small excess of acetic acid will redissolve some of the albumin; again, if mucin be present acetic acid will not dissolve it, whereas nitric acid does.

For accurate work the above quantities and dilutions must be strictly adhered to. For purposes of comparison, two test tubes of equal amount of the clear urine should be used; one treated as above, the other used as a control. Certain drugs, such as turpentine, copaiba, and sandalwood, cause a similar cloudiness; but if alcohol be added, on cooling of the urine this cloudiness will disappear if it is not due to albumin.

The next test, that of Heller, is performed as follows: Place 5 c.c. of concentrated nitric acid in a test tube; add carefully, without mixing, an equal amount of the filtered urine. A distinct white disc will appear at the junction if albumin is present. It is necessary to wait about three minutes before a negative result can be read off, since the formation of the disc may be retarded if the quantity present is very small. No other precipitate will appear in the shape of the above-mentioned disc; any cloudiness due to other substances appears some distance from the junction of the two fluids, leaving no possible doubt if the test has been performed with neatness.

We have thus two very simple methods that give us all the information required, and it is always best, in doubtful cases, to perform them side by side. There is no necessity to resort to the more modern and more complicated methods, as greater accuracy than that given by the above two tests is never required in practice, and they at least have no pitfalls.—*Australian Medical Gazette*, November, 1912.

---

**The Overweight** finds no greater favor in the eyes of insurance officers in England than he does in America. Mr. Lewis P. Orr, an English actuary, writing on "Insurance Research and Eugenics" in the *Eugenics Review* for January, 1913, says that the corpulent must go, or rather he must no longer come, and as obstacles to his coming Mr. Orr looks to the eugenist and the physician—the eugenist to prevent inherited corpulency and the physician to see that it is not acquired. His prejudice against the fat, from the insurance point of view, is based upon the statistics presented by Symonds and others in this country, which show that among the corpulent risks—those whose abdominal measurement is greater than that of the chest—the deaths are from 18 to 52 per cent. above the expectation. The writer believes that a campaign against overweight can be successfully waged, and he hazards the opinion that the day may be looked forward to "when the fat man will be largely extinct—outside the showman's booth." Mr. Orr is an optimist.

# Book Reviews.

GRUNDRISS DER PSYCHIATRISCHEN DIAGNOSTIK, nebst einem Anhang enthaltend die für den Psychiater urchtigsten Gesetzerbestimumungen und eine Nebersicht der gebrancht lichsten Schlafmittel. Von Prof. Dr. RAECKE, in Frankfurt a. M. Mit 14 Textfiguren. Dritte vermehite und verbesserte Axiflage. Preis 3 m. Berlin: August Hirschwald, 1912.

THIS third edition of a very-practical little book on psychiatric diagnosis is an improvement on former editions in that it shows thorough revision and the addition of some new matter. The various methods of testing the vestibular apparatus are briefly described in this edition; intelligence tests for the child are also added; and suggestions for the study of simulations are more fully elaborated. Those who read German will find the book useful. The classification used by Siemerling is employed. Those accustomed to the classification of Kraepelin will be able to follow it.

HOUSEHOLD BACTERIOLOGY, for Students in Domestic Science. By ESTELLE D. BUCHANAN, M.S., Recently Assistant Professor of Botany, Iowa State College, and ROBERT EARLE BUCHANAN, Ph.D., Professor of Bacteriology, Iowa State College, and Bacteriologist of the Iowa Agricultural Experiment Station. Price, $2.25 net. New York: The Macmillai Company, 1913.

THIS volume is said to consist of a revision of lectures given for several years to students in Home Economics at the Iowa State College and presents ample evidence of the excellence of this course. The general sections on classification, morphology, physiology, etc., are treated in a clear and comprehensive manner. The essential part of the work, however, is the section devoted to fermentation, which discusses concisely the relation of microorganisms to natural and prepared foods. The section on microorganisms and health is naturally much condensed but contains four valuable chapters on the contamination of water, air, milk, and foods. This rst work devoted to the bacteriology of Domestic Science constitutes a distinct addition to the literature and will be found to be of marked value. The average intelligent housewife could read it with appreciation and profit.

VACCINE THERAPY, Its Theory and Practice. By R. W. ALLEN, M.D., B.S. (Lond.), Late Clinical Pathologist to the Mount Vernon Hospital for Disease of the Chest; Late Pathologist to the Royal Eye Hospital; Late Gull Student of Pathology, Guy's Hospital. Fourth Edition. Price, $3.00 net. Philadelphia: P. Blakiston's Son & Company, 1913.

THE medical profession is frequently accused of being made up to a large extent of faddists who, with unrestrained enthusiasm, take hold of a theory or method of treatment, carry it far beyond any logical or orderly development and advocate it at all times. Finally something new appears, the bubble bursts, and the old is thrown entirely away, the majority being blind to its value and blaming the theory for the results of unskillful application. The average man will have little idea of the extent of the development of vaccine therapy until he sees recorded in this volume the enormous number of diseases in which it has been practised. It is to be hoped that this valuable therapeutic measure will not suffer at the hands of its too enthusiastic supporters. This edition has been completely rewritten, since the subject has undergone such marked changes in the two years which have elapsed since the appearance of the third edition. The author adheres closely to the teachings of Wright except that he considers the opsonic index to be more of theoretical interest than of practical assistance in using vaccines. The greater portion of the volume is occupied with discussion of the vaccine treatment of various diseases far too numerous to mention. Minute directions are given for the preparation of the vaccines used.

FRANZ KÖNIG, LEBENSERINNERUNGEN. Price, 2 Marks. Berlin: Aug. Hirschfeld, 1912.

THE book contains an excellent reproduction of a portrait of the author and reminiscences written down by the author at the time of their occurrence. From these were omitted those circumstances which would affect persons still living and also those of interest to the smallest family circles only. An inactive period of six years from the time of the author's retirement from active life to its close is conspicuous by the absence of any personal notes. Life without a purpose was considered as almost wholly useless. This period is filled by small sketches penned by the son of the deceased. The book concludes with a speech of appreciation for the author's life and work by O. Hildebrand delivered on the 16th of February, 1911, in the Surgical Clinic at the Charité, Berlin.

ROBERT KOCH, eine biographische Studie von Dr. KARL WEZEL, Stabarzt an der Kaiser Wilhelms-Akademie fur das militararztliche Bildungswesen. Mit einen Porträt und 5 Abbildungen im Text. Price, 3.60 Marks. Berlin: Verlag von August Hirschwald, 1912.

THE author in this work gives us a clear idea of the individuality of the man and his great contribution to science as a small outward sign of the deep gratitude and the steadfast loyalty which the German Officers' Sanitary Corps feels for its master teacher and friend. The name of Robert Koch is inseparable from the history of modern hygiene and bacteriology. He is not only the real founder of bacteriology but also a real reformer of modern hygiene. The immediate result of his discoveries and those of his pupils brought about a revolution in the whole field of the preservation of health and the prevention of ravaging pestilence. As late as 1874 Billroth wrote that at the time there was no morphological proof that micrococci or bacterial forms could be held responsible for the development of a certain disease in or on the body. Two years later Koch published his phenomenal works, which were the marvel of the scientific world of the time, and brought light, clearness, and knowledge upon the secret connection between cause and effect. By the application of his new method he succeeded in determining the causal relation between a characteristic bacteria or spore and the definite disease which it causes.

VERÖFFENTLICHUNGEN DER ROBERT KOCH-STIFTUNG ZUR BEKÄMPFUNG DER TUBERCULOSE. Price, 4 marks. Leipzig: Georg Thieme, 1912.

I. UBER DIE BEHANDLUNG DER TUBERKULOSE MIT KOCH'S ALBUMOSEFREIEM TUBERCULIN. Von Prof. Dr. G. JOCHMANN, leitender Artz der Abteilung für Infektionskrankheiten am Rudolf Virchow-Krankenhaus in Berlin, und Stabarzt Dr. B. MÖLLERS, Komm. zum Institute für Infektionskrankheiten. This albumen free tuberculin is a specific efficacious preparation which is made from a culture fluid free from albumen in contradistinction to the old Koch albumin tuberculin. It therefore contains only those albuminous products which are formed by the tubercle bacillus during its development, which is partly given off to the nourishing medium from the live cultures and in part from that which is freed from the living cultures by autolysis from the dying bacteria. The subjective symptoms after the injection of this new preparation are less marked than those produced by the older. The curative results are good, well fitted for ambulatory patients because of the slight reaction. A marked increase of complement binding antibodies is usually not produced which observation has also been made with the old tuberculin.

II. UBER DIE STOMACHALE ANWENDUNG VON TUBERCULINPRÄPARATE. Von Dr. B. MÖLLERS, Komm. zum Institute für Infektionskrankheiten, und Dr. W. HEINEMANN, Assistenzarzt am Rudolf Virchow-Krankenhaus.

THE authors found that it is possible to give tuberculin in capsules which resist digestion in the stomach but are dissolved in the intestines under the action of the digestive juices. Pepsin and trypsin diminish the specific action of the tuberculin. The method is unreliable for diagnostic purposes.

III. VERSUCHE MIT CHINOSOL UND FORMALDEHYDE BEI TUBERCULOSE. Von Dr. KURT BLÜHDORN, chem. Assistenzarzt am Rudolf Virchow-Krankenhaus in Berlin.

THE author found that neither chinosol nor formaldehyde, nor both substances together, even under the most favorable experimental conditions and by the use of large doses for injection, are capable of preventing the occurrence of tuberculosis or its fatal ending.

VERÖFFENTLICHUNGEN DER ROBERT KOCH-STIFTUNG ZUR BEKÄMPFUNG DER TUBERCULOSE. HERAUSGEGEBEN VOM VORSTAND DER STIFTUNG. Heft 4, pages 54. Price, 4 Marks. Leipzig: Verlag von Georg Thieme, 1913.

I. Studien uber spontane Kaninchentuberculose. Von Stabarzt Dr. ROTHE, früher kommandiert zum institute.

II. Beitrage zur Frage des grannlaren Tuberculosevirus. Von Dr. R. BITTROLFF, Assistent am hygienischen Institute, unde Dr. K. MOMOSE, Generaloberarzt der Kaiserl. japanischen Marine.

III. Uber den Typus der Tuberkelbazillen bei Parinaudscher Erkrankung (Conjunctivitis tuberculosa). Von Stabarzt Dr. B. MÜLLERS, kommandiert zum Institut.

The Division of Child Hygiene of the Department of Health of the City of New York. By S. Josephine Baker, M.D., Director of Child Hygiene. Monograph Series, No. 4. New York: Department of Health of the City of New York, 1912.

This monograph describes the Division of Child Hygiene of the Department of Health of the City of New York, including its history, organization, functions, methods, and results. The activities of this important division of health administration are concerned with midwives, infant mortality, foundling babies, day nurseries, institutions for dependent children, medical inspection and examination of school children, and employment certificates. This useful monograph has been published for general distribution.

The Practice of Dentistry. A Practical Treatise Upon the General Practice of Dentistry, Operative and Prosthetic, Exclusive of Orthodontic Practice. By Leo Greenbaum, M.D., DD.S., formerly Dean and Professor of Clinical Dentistry, Materia Medica and Anesthesia, in the Philadelphia Dental College; and Max Greenbaum, DD.S., Formerly Quiz Master in the Philadelphia Dental College. With 350 illustrations. Price $6.00. New York and London: D. Appleton & Company, 1912.

The time has vanished when physicians took no interest in the work of the dentist, and when the dentist ignored the value in his vocation of a broad foundation of medical training. A book on the practice of dentistry, such as the volume under review, shows how in many respects the professions of medicine and of dentistry interlock and overlap one another. It is strange that up to the present time there has been written no volume dealing with the general practice of dentistry. In order to fill this gap the authors have written a work that is designed to meet the practical requirements of the active dental practitioner, by detailing the most advanced developments and methods in his work. The book consists of two sections, the first dealing with operative dentistry, the second with prosthodontia. In the first section the chapter headings are as follows: Dentition: the Factors and Periods of Eruption of Deciduous Teeth; Dentition of the Permanent Teeth; Dental Caries: History and Etiology; Dental Caries: Pathology; Treatment of Dental Caries and Preparation of Cavities; the Treatment of the Deciduous Teeth; Inlays: Indications for Their Use, and the Cavity Form; Construction of the Porcelain Inlay; the Construction of the Gold Inlay; Hypersensitive Dentine; Erosion; Pyorrhea Alveolans; Filling Materials; Diseases of the Dental Pulp; Diseases of the Pericementum; the Conservation of the Dental Pulp; the Removal of the Dental Pulp; Root Canal Filling; the Exclusion of Moisture During Operations; the Separation of Teeth Preparatory to Filling; Oral Hygiene; the Discoloration of Teeth; the Plantation of Teeth; and the Extraction of Teeth. The section on Prosthodontia comprises the following topics: The Study of the Mouth Prior to Taking the Impression; Selecting the Base and Form of Denture; Impressions; Casts; Dies and Counterdies; Swaged Metallic Plates; the Bite; Vulcanized Rubber as a Base for Artificial Dentures; Artificial Crowns; Bridgework; Cast Dentures of Aluminum and Fusible Alloys; Continuous Gum Dentures and Palatal Mechanism. The physician will find much in this volume to interest him, particularly on the subject of oral hygiene. The progress in the use of inlays is fully discussed. There are many helpful illustrations and in this and in other respects, such as the excellent paper and typography, the volume is one that cannot be too highly commended. On the other hand the style of the authors, while aiming at elegance and dignity, has sacrificed simplicity and is apt to be cumbrous and unduly verbose. This is an imperfection of no great moment in a work of this kind.

A Guide to Some of the Hygienic Features of New York City. Prepared for the XV. International Congress on Hygiene and Demography. By Charles F. Bolduan, M.D., Assistant to the General Medical Officer, Monograph Series, No. 6. New York: Department of Health, City of New York, 1912.

The subjects discussed in this excellent summary of the hygienic features of New York City are the following: Historical and Governmental; Department of Health; Municipal Milk Stations in New York; Water Supply; Street Cleaning; Sewage; Hospitals; Board of Ambulance Service; Disposal of the Dead; Public Baths; Children's Playgrounds; Correctional Institutions; Quarantine of the Port of New York; Physicians' Medical Education; Control of Immigration; Scientific Institutions, and Directory of the Department of Health. This paper has been published for general distribution.

Traité International de Psychologie Pathologique. Directeur: Dr. A. Marie (de Villejuif). Comité de Rédaction: MM. les Professeurs Bagenoff (de Moscou), Bechterew (de St. Pétersbourg), Clouston (d'Edinbourg), Déjerine (de Paris), Grasset (de Montpellier), Lugaro (de Modène), Dr. Magnan (de Paris), Pilcz (de Vienne), Ziehen (de Berlin), Tome Troisième, Psychopathologie Appliquée. Par MM. les P'rs Bagenoff, Bianchi, Sikorsky, G. Dumas, Havelock-Ellis, Dr. Cullerre, A. Marie Dexler, F. Helme, P'r J. Wertheim Salomonson. Avec 338 gravures dans le texte. Paris: Librairie, Felix Alcan, 1912.

This is the third and last volume of an important work by many collaborators of eminence in the field of psychiatry in Europe. The first volume appeared in 1910, and was on general psychopathology. The second appeared in 1911, and was on clinical psychopathology. Each contained, like the present work, over a thousand closely printed pages. The first two volumes have already been reviewed in these columns. There are four chapters in the present volume. The first chapter comprises "General Considerations on the Physio-Pathology of the Sensorial Sphere," by Bianchi; and "Morbid Mentality from the Psychologic Point of View," by Sikorsky. Sikorsky's presentation is more or less new, and is of great interest, not only clinically and philosophically, but also as a study in ethnology, art, and physiognomy. There is an appendix to this chapter, on "Pathologic Sadness and Joy," by Dumas; and "Psychopathic Sexuality," by Havelock-Ellis. The second chapter (on comparative psychopathy) embraces a delightful discussion of "Madness in History," by Cullerre; and essays by Marie, Bagenoff and Dexler, on "Ethnic Psychopathology" (Asia, Africa, American Indians, etc.); "Collective and Morbid Psychology" (mental contagion, etc.); and the "Principal Characteristics of the Morbid Psychology of Animals" (higher mammalia). Chapter three is on "the General Etiology of Psychopathic Troubles," by Marie, and includes cosmic influences (barometric, thermic, electric, etc.), and social causes (crises, toxic, bio-physiologic, etc.). The fourth and last chapter is devoted to the practical application of the methods of the laboratory to the study of psychiatry. This embraces: Experimental Psychology in its Relations to Psychiatry (psychometry, psycho-physiology, and psychoanalysis), by Marie and Helme; and the uses of electricity in neurobiologic examinations in psychiatry, by Salomonson.

In the opinion of the reviewer, this volume, added to the two which have preceded it, forms a monumental work which should be in every public library, for reference not only by the psychiater and neurologist, but by any educated person who may be interested in either the normal or the disordered mind. As A. Marie truly says, "The sick man is a near neighbor of the man who calls himself normal. Physiology and pathology differ only by degrees and insensible transitions. All things concerned with psychopathology, whether in time or space, in history or in race, in higher animals or in man, have the same laws of general unity. * * * The microcosm of the insane asylum is but a caricature of the normal world."

Cancer: The Problem of Its Genesis and Treatment. By F. W. Forbes Ross, M.D. (Edin.), F.R.C.S. (Eng.), D.P.H. (Lond.), late Civil Surgeon His Majesty's Guards' Hospital, London. Price 5s. London: Methuen & Co., 1912.

Dr. Ross's thesis is that cancer is due to a want of balance in certain mineral salts of the body, such want leading to disorderly and malignant growth of epithelial cells. The special salts singled out by the author are those of potassium, and the data which have led him to this assumption consist mostly of personal clinical observations, the most important of which, in his estimation, is "that actually not one single case of cancer has ever to his knowledge occurred amongst the clientele of his practice." This freedom from malignant disease among his patients he attributes to the use of "an enormous quantity of potassium citrate, bicarbonate, and hypophosphite, where other doctors have used sodium."

It must be granted, of course, that in our present ignorance of the specific causation and the specific therapy of cancer, Dr. Ross's theory has the same *raison d'être* as many other old and new theories of cancer. We must confess, however, that the proofs given by the author in support of his views are not at all as convicing as he seems to believe. Mere rarity of cancer in the author's practice and the supposed beneficial action of certain potassium salts in a few cases treated by him are hardly sufficient: the remaining evidence brought forward is of too theoretical a character to mean very much in the support of his contentions.

# Society Reports.

## NEW YORK NEUROLOGICAL SOCIETY.

*Stated Meeting, Held at the New York Academy of Medicine, February 4, 1913.*

THE PRESIDENT, DR. SMITH ELY JELLIFFE, IN THE CHAIR.

**Tumor of the Base of the Brain Immediately Behind the Pituitary Body.**—Dr. H. CLIMENKO reported this case. The patient was a girl, nine and a half years old, of Jewish parentage, born in the United States, who came under his observation on November 10, 1912. The family history was unimportant. Personal history: The patient was delivered instrumentally and was breast fed. Teething occurred in the seventh month, and she began to speak and walk when about a year old. She attended school until her present illness, and was of average intelligence. She had whooping cough at the age of four years and measles a year later. For the past twelve months the child had suffered from unusual thirst and occasional vomiting, although these symptoms were not of sufficient severity to interfere with her regular school work. The attending physician had not found anything abnormal in the urine. About six weeks ago she developed an alveolar abscess of the right lower molar; the abscess was incised, and a few days later the tooth was extracted. On the following day, ptosis of the right eyelid was noticed, and two days later a similar condition developed on the left side. She began to suffer from intense headaches and profuse vomiting. Examination by Dr. Climenko showed a pale emaciated child of normal size and good development. Her station and gait were negative. All the tendon reflexes were increased; no Babinski; no clonus. The abdominal reflexes could not be elicited. No sensory disturbances. Smell was unaffected. There was complete bitemporal hemianopsia, with pallor of the optic discs. There was complete ophthalmoplegia of the left eye, and the right eyeball was drawn outward. Both pupils were widely dilated and failed to react to light and accommodation; the other cranial nerves revealed no abnormalities. The heart, lungs and abdominal viscera were negative. With the above symptoms, the following possibilities as to diagnosis were thought of: (1) A toxic neuritis of the ocular and optic nerves. (2) An empyema of the body of the sphenoid. (3) An encephalitis of specific origin. (4) Tumor. The patient was admitted to the Mt. Sinai Hospital, where she was seen by Dr. I. Abrahamson. The blood and spinal fluid were examined with negative results as to the Wassermann test. An *x*-ray examination, made by Dr. L. Jaches showed a marked depression of the middle fossa of the skull, presenting a trough-like appearance, while the posterior clinoid process was pushed forward, narrowing the upper part of the sella turcica. With these findings, the diagnosis of a tumor of the base of the brain was established. This patient, Dr. Climenko said, was at present in the Neurological Hospital on Blackwell's Island. The headaches and vomiting had disappeared completely for the past few weeks, but the child was extremely emaciated and totally blind. No other symptoms had developed.

Dr. I. ABRAHAMSON said the case reported by Dr. Climenko was first looked upon as one of toxic ophthalmoplegia, with beginning atrophy of the discs. A little later, when the atropine had worn off, it was noted that the pupils remained widely dilated, did not contract to light, etc., and they then knew that they were dealing with a condition directly involving the nerves themselves. The *x*-ray cleared up the diagnosis, revealing a tumor behind the sella turcica.

**A Case for Diagnosis.**—Dr. CLIMENKO presented a married woman, 46 years old; born in Russia. The only point of interest obtainable in the family history was that the mother and two sisters were "very nervous." The patient's previous history was negative. She passed the menopause two years ago. When the patient was first seen by Dr. Climenko, six years ago, she gave the following history: Two years ago she was awakened one night with a peculiar sensation in the right upper extremity; she felt as though a shock of electricity had passed from her shoulder to her toes. This lasted only a few minutes, and after that she was unable to move the right upper extremity; it hung powerless by her side for a few minutes only, soon afterwards assuming its normal function, and on the following day she was able to work. Two months later she had a similar attack, but this was of longer duration. Since then these attacks became more frequent and lasted for a longer time. She consulted a physician, who advised hypodermic injections of strychnia, with massage and electricity. This treatment, the patient claimed, aggravated her condition, and subsequently she complained of weakness and inability to use the right arm. Physical examination revealed a hypertrophy of all the muscles of the right upper extremity. The reflexes were unchanged; there were no sensory disturbances; no change in the electrical reactions. There was diminution of the gross motor power in the arm, and inability to execute the finer movements (picking up a pin, threading a needle, etc.) with the right hand. No other symptoms were present. Six years later, when the patient again consulted Dr. Climenko, she complained of total disability of the right upper extremity, with paresthesias and tonic contractions in the flexors of the arm on attempting to flex the forearm. A physical examination at this time showed enormous hypertrophy of all the muscles of the right upper extremity, but particularly of the flexors of the forearm. The right upper extremity was one inch larger than the left. The electrical tests showed a normal nerve reaction, but a remarkable hyperexcitability to both galvanic and faradic currents, without any qualitative change. There were myotonic contractions of the biceps at each attempt to flex the forearm, either actively or passively. Direct myotonic irritability was increased, and fibrillary twitchings were present in the flexors of the forearm. There were no sensory disturbances. There was weakness of the entire right upper extremity, and inability to use the hand. There were no other nervous symptoms. The blood pressure was 150 mm. The heart and lungs were normal; the urine negative, as was also an *x*-ray examination of the spine and upper extremities.

Dr. ABRAHAMSON said the case shown by Dr. Climenko was unique. The enlargement of the right upper extremity had now persisted for six years, and the bones and muscles, skin and integument were involved, and in addition to this, there was a distinct myotonia. The speaker said the case appealed to him as an unusual type of syringomyelia, a syringomyelia myotonica cum macrosomia, with the involvement of two distinct cord areas, producing both a myotonia and a macrosomia. There was also a slight enlargement of the right face, the right side of the forehead being more prominent than the left. Frankl-Hochwart many years ago called attention to a syringomelia with intentional spasms; but here distinct myotonia was absent.

**Air in the Ventricles of the Brain Following a Fracture of the Skull.**—Dr. W. H. LUCKETT reported this case. The patient was a machinist, a white man, 47 years old, who was admitted to the Harlem Hospital on November 24, 1912, shortly after he had been struck by a trolley-car and thrown to the pavement. On admission, he was conscious and rational. The pupils reacted equally to light. There was a right sub-conjunctival hemorrhage. There was a lacerated wound over the right eyebrow, connecting with a circular fracture of the frontal bone just above the orbital ridge. The tongue was covered with a bloody fluid, probably cerebrospinal fluid. A diagnosis of fracture of the skull was made and confirmed by two *x*-ray plates by Dr. W. H. Stewart. The patient was prepared for immediate operation, but his symptoms cleared up so rapidly that it was decided to wait. On the fourth day he was sitting up in bed; on the seventh he was out of bed, and five days later he left the hospital contrary to advice and under protest. One week later, on December 12, 1912, he was readmitted with the history that two days previously he had a severe headache, with occasional vomiting. Up to that time he had been reading the papers daily, although he was dull and listless and would not converse with anyone, and took no notice of his surroundings. For the past few days he had not replied when spoken to, although he understood what was said to him. Two days after his readmission to the hospital the patient was examined by Dr. William M. Leszynsky. At this time the man was conscious; he answered questions and obeyed commands intelligently; cerebration was slow and he was inclined to lapse from time to time into a condition of mental confusion; there was no aphasia at this time; no disturbance of speech; no astereognosis; tremor of tongue and hands. The pupils were normal and reacted equally. Facial innervation and motility of the tongue were normal. No tenderness on percussion over skull. No rigidity of neck. Upper extremities normal; the lower extremities showed no paresis or rigidity, but were resistive to examination. Both knee jerks were increased, especially the right. Diagnosis, increased intracranial pressure; probably abscess. A blood count, made on December 13, showed 15,900 leucocytes, with 86 per cent. of polymorphonuclears and 8 per cent. of lymphocytes. An ophthalmoscopic examination, made on the same day by Dr. M. Cohen, showed that the external ocular muscles of both eyes were normal,

with a slight sub-conjunctival hemorrhage in the right temporal quadrant. In the right fundus, the veins were enlarged and tortuous, with the central vein markedly dilated over the disc and also at the exit from the nerve. The arteries were slightly contracted. The disc borders were indistinct, due to marked edema. In the left fundus the veins were also markedly dilated; the arteries were contracted, the disc borders were indistinct and there was a suspicion of retinal hemorrhage. Diagnosis, bilateral optic neuritis indicative of intracranial pressure. A second series of *x*-ray pictures taken by Dr. Stewart showed that the ventricles of the brain were enormously dilated with what was probably either air or gas, and the patient apparently getting worse, a right-sided subtemporal decompression was done by Dr. Luckett on December 16. Upon exposure, the dura did not bulge and was not particularly tense. No fluid escaped on incision of the dura and pia; a slight meningitis was noted. A needle was then passed into the anterior horn of the lateral ventricle, and the removal of the trocar was followed by two or three quick spits of air and fluid, and then clear cerebrospinal fluid to the amount of eight c.c. Because of the presence of a slight meningitis, the large quantity of fluid and the presence of air in the ventricles, it was determined to drain them. Accordingly, the patient was now turned over on his face, and a suboccipital operation was performed. The bone was exceedingly thin. The dura was incised, and then the pia into the cisterna magna, and immediately there escaped considerable clear fluid, generously admixed with bubbles of air. A small piece of twisted rubber tissue was inserted as a drain. The patient did well until the fourth day after the operation, when his temperature suddenly went up to 107 and he died. At the autopsy, which was performed by Dr. Otto H. Schultze, air was shown to be present in the ventricles when they were incised with the brain submerged in a vessel of water. There was a lacerated wound of the base of the right frontal lobe just beneath the right anterior horn and just over the fracture in the orbital plate that communicated with the frontal sinus. It was subsequently learned that air was probably forced up through the fracture in the frontal sinus into the ventricles during an attack of sneezing. In connection with the case, Dr. Luckett exhibited a number of radiographs demonstrating the presence of the air in the ventricles of the brain.

Dr. William M. Leszynsky, who had made an examination of the patient before the operation, said he had found it impossible to determine the cause of the intracranial pressure, although he was inclined to the view that the patient might be developing a cerebral abscess. This idea was dispelled, however, by the *x*-ray plates, which showed a very unique picture; unlike anything, so far as he knew, that had ever been recorded.

**Some Anomalous Tremors.**—Dr. Smith Ely Jelliffe showed two cases to illustrate some anomalous types of tremors. They were patients from Dr. Hammond's and his own service at the Post-Graduate Hospital. The first patient was a woman, twenty-nine years old, with a tremor of the left hand which was continuous during the day, disappearing during sleep. The tremor had come on gradually about seven months previously. Its rate was from 5-6 to the second, and had little intention quality. There was also a slight inequality in the pupils, but no modification of the reflexes. Negative Wassermann and negative throughout otherwise. The eye grounds were normal. The second patient, a woman, thirty-four years old, had a tremor which began fourteen years previously in a manner very similar to that illustrated in the first case. It began in one hand and gradually became generalized, until now it involved almost the entire body. There was marked stiffness and a tendency to retropulsion at times. There were no palsies nor sensory changes, excepting that the sole of the left foot showed a slight diminution to light touch. All the reflexes were fairly active; there was no distinct Babinski. The eyes showed a slight inequality of the pupils, which was also present in the first case, and a very distinct pallor of the temporal side of both discs. The fields were normal; there was no nystagmus. There were no speech defects. The patient was a sensible, intelligent young woman, and careful analysis by Dr. Beatrice Hinkle failed to show any complex constellations. She had gradually lost weight, but there was no appreciable diminution in muscular power.

Dr. B. Sachs said he regarded the first case as one of paralysis agitans and the second as one of multiple sclerosis. The first case he thought was absolutely typical of paralysis agitans: There was no other type of tremor that it could be mistaken for, and the only one that could be at all compared to it was an occasional functional tremor. The speaker said he recalled one such case where the husband had paralysis agitans and the wife developed a very similar functional tremor. In the case shown by Dr. Jelliffe the woman had the facies of paralysis agitans, and had no symptoms which would lead one to think of any other diagnosis. As to her age, twenty-nine years, that would not necessarily militate against the diagnosis, as paralysis agitans may have its onset in early life. The speaker said that in his book he had recorded a case of paralysis agitans in a young man coming on about the age of eighteen or twenty; in that case the patient eventually developed all the symptoms of a disseminated sclerosis, although at their onset they were quite characteristic of paralysis agitans.

As to the second case, Dr. Sachs said he thought there was no doubt that it was an example of multiple sclerosis. The woman had a tremor which became worse on exertion, and she had just a slight tremor—an unconscious tremor we might call it—of the head and neck muscles, which we did not see in paralysis agitans. This was very significant of multiple sclerosis. She had also had a pallor of the optic discs and some monotony of speech.

Dr. Abrahamson, speaking of Dr. Jelliffe's second case, said it reminded him of a girl who was a patient at the Montefiore Home, excepting that that patient was somewhat spastic. He thought, however, it belonged to the same category. In these cases we probably had to deal with a diffuse lesion in the mid-brain in the nucleus rubra and the crus, and very likely with involvement of the rubrospinal system.

Dr. J. Ramsay Hunt said that in the first case shown by Dr. Jelliffe, on passive motion, there could be elicited a slight interrupted rigidity of the muscles. This was a phenomenon to which Dr. Moyer had applied the name of the "cogwheel" symptom of paralysis agitans, and in early cases the speaker thought it was of distinct value—these slight interruptions on making passive movements. As to the second case, Dr. Hunt thought a positive diagnosis could not be made. That offered by Dr. Sachs would be a probable working one; at the same time the speaker said he was inclined to regard it as a case of progressive degeneration; perhaps, as Dr. Abrahamson had suggested, in the pyramidal tracts.

Dr. Leszynsky said the unusual factor in the first case shown by Dr. Jelliffe was the age of the patient. The character of the tremor was not at all unusual, as the speaker said he could recall perhaps half a dozen cases where it was unilateral, being confined to one hand for many months. When the patient's attention was directed to the opposite hand, the tremor on the affected side increased, which was quite characteristic in paralysis agitans. As to the second case, Dr. Leszynsky said he did not think much stress could be laid upon the pallor of the discs, as ophthalmologists frequently differed in their view of its significance—whether it was pathological or physiological. In this case there was apparently no disturbance of the field of vision. Personally, he would favor the diagnosis of paralysis agitans.

Dr. Edward D. Fisher said he had seen a case very similar to the first one shown by Dr. Jelliffe, where there was evidently a lesion in the crural tract, but in the case he had in mind the tremor was constant and increased on motion. As to the second case, Dr. Fisher said he would be inclined to look upon it as a paralysis agitans rather than a multiple sclerosis.

Dr. B. Onuf suggested that in the second case there might be a diffuse brain sclerosis instead of a multiple sclerosis.

Dr. M. Neustaedter said that about two years ago he reported the case of a man twenty-eight years old who after a shipwreck developed a tremor of one hand, the nature of which was at first uncertain. It was finally shown to be a case of paralysis agitans, as proven by the tremograph.

Dr. L. Pierce Clark said the two cases shown by Dr. Jelliffe impressed him very much as they had Dr. Sachs and for the same reason. He was surprised to hear from the discussion that paralysis agitans should be looked upon as such an entity, and he thought it was rather premature to insist upon an anatomical basis for that disease. In the first case, the tests showed that there was a distinct alteration of the vibrations to the intention type of tremor. He thought this was a case of paralysis agitans, while the second was one of disseminated sclerosis. The speaker said he saw a case of paralysis agitans at the Vanderbilt Clinic in a man twenty-nine years old, although these patients look older on account of the mask-like expression of the face.

Dr. Sachs said he had never seen a rapid tremor that he could account for by any midbrain lesion.

Dr. JELLIFFE, in closing, said these two cases were shown for the express purpose of bringing out such a discussion as had been elicited. He felt that one was justified in inferring that both cases were of a similar type, and that the first case represented the beginning stage of what might ultimately develop into the condition of the second case. He was inclined to believe that in both cases the process was one of multiple sclerosis, but one which was localized at first and primarily in the midbrain structures. Here we had midbrain, or paralysis agitans, types of multiple sclerosis, the multiple sclerotic area involving those pathways which in the more recent works on this subject were referred to as being involved in paralysis agitans. As to the character of the tremor, Dr. Jelliffe said at least three different types of tremor originating in the midbrain structure, depending on the point of interruption of the mechanism, were to be distinguished. These were the athetoid, the paralysis agitans like, and the intentional tremor. From the more recent studies of this subject we were able to say in just what portion of the arc the mechanism was interrupted. In both of the cases he had shown, Dr. Jelliffe said, the tremor was like that of paralysis agitans. The presence of vasomotor signs indicated possibly the implication of the thalamus, while the eye signs pointed to lesions located near the red nucleus.

**Address of the Retiring President.**—Dr. L. PIERCE CLARK, in retiring from the presidency, briefly sketched the work of the society during the past two years and emphasized the importance of giving more attention in the future to the beginning neuroses and psychoneuroses, the milder forms of the frankly established insanities, and more especially to the causation and treatment of such. He felt sure that if this plan was more generally followed, the discussions of the papers would take on a broader and deeper trend. He also suggested that the case presentations be made more thorough, and that some provision be made, if possible, for those members who were interested to look over the clinical material before the general discussion was called for in open meeting.

**A Summary of the Origins, Transformations, and Present-Day Trends of the Paranoia Concept.**—Dr. SMITH ELY JELLIFFE made this the subject of his Presidential Address (see page 599).

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON OBSTETRICS AND GYNECOLOGY.

*Stated Meeting, Held January 23, 1913.*

DR. GEORGE GRAY WARD, JR., IN THE CHAIR.

**Operation for Marked Descensus of the Uterus by the Dührssen-Bandler Method.**—Dr. SAMUEL WYLLIS BANDLER presented this patient. She was 47 years of age and had descensus of the uterus associated with a very large cystocele, a decided enterocele, and rectocle with complete absence of any perineal body. This patient was operated on before the Surgical Congress by the Dührssen-Bandler method. A vaginal fixation of the fundus of the uterus to the anterior wall was done with the aid of an inverted "T"-shaped incision. There was also a high amputation of the cervix and a sewing of the posterior fornix and the pelvic connective tissue around the new external os in such a way as to diminish the diameter of the anterior and posterior fornix. In consequence of this a considerable area of the anterior vaginal flaps was removed. Next a resection of the entire posterior vaginal wall in its entire length was done and this was followed by the Bandler form of perineorrhaphy, which included three buried chromic sutures to unite the levator ani muscles of the two sides in front of the rectocele, and anchoring of the posterior vaginal wall at this point. The perineorrhaphy was completed by a figure of eight stitch which served to bring the raw surfaces together at the middle line.

The Chair then appointed a committee to examine the patient and to report back to the Section on their findings.

Dr. BOLDT said that so far as the results were concerned they were perfectly satisfactory. This patient had come to his clinic and he had turned her over to Dr. Bandler. She had an exceptionally large cystocele; the entire wall with part of the bladder protruded out of the vulva, the mass being as large as a small orange. The cystocele operation had given an absolutely perfect result, but he did not consider that the patient had a prolapse of the uterus when he examined her. It was only a moderate descensus.

Dr. THOMAS TYLER SWEENY said that the operation performed by Dr. Bandler seemed to have removed the cystocele, but the fundus of the uterus rose higher in the abdomen than it did after the Dührssen operation. The vagina seemed to him to be a little shortened.

Dr. FREDERICK C. HOLDEN said that his findings agreed with those of Dr. Boldt and Dr. Sweeny. There was a firm pelvic floor and the cervix was well back in the hollow of the sacrum.

**Case of Ectopic Gestation with Slight Hematocele Operated Upon Before the Surgical Congress.**—Dr. BANDLER reported this case. The history of the case and the diagnosis was tuboovarian inflammation. When examined under anesthesia the mass seemed to be harder, and as the fingers were applied over the abdomen and pressed down they passed between this mass and the uterus, and the separation of little tiny bands yielding to the pressure was distinctly felt. This was decidedly in favor of an ectopic mass. A possible diagnosis of dermoid was made and the operation was done vaginally There was little free blood and not many clots in the peritoneal cavity, yet the typical bluish shimmer was present as soon as the vesicouterine fold of peritoneum was reached. Even then ectopic gestation was referrd to in a rather doubtful way. On entering the peritoneal cavity a few black clots were seen. The tube was grasped by a sponge holder and drawn into the vagina, the outer end with its enlarged ovary, forming a continuous mass, impinged against the anterior speculum and it was impossible to bring the large tumor into view. The appearance of the mass, therefore, showed it to be a tube filled with hard clotted blood. The dressing forceps perforated the outer end of the tube to permit some of the coagulated contents to be expelled and thus diminished the size of the mass. Clamps were applied to the edges of this perforation and gradually the large ectopic mass was brought into the vagina, where it was easily removed.

**Ectopic Gestation with Large Hematocele.**—Dr. BANDLER reported these two cases. The first patient was 22 years of age and had given birth to one child three and one-half years ago. Menstruation was expected on November 18. Two days before this time she was seized with sharp cramps in the lower abdomen which lasted a day and were followed by bleeding. At the time of her admission to the hospital, three weeks later, she gave a typical history of ectopic gestation. Examination showed the cervix hard, large, and fairly movable; the uterus was enlarged and movable, and there was tenderness in the right iliac region Examination under the anesthetic before operation gave the sensation of a large hematocele surrounding a firm tube. When the peritoneum was exposed there was a typical blue shimmer which Dr. Bandler said he had observed in every case of ectopic gestation operated upon through the vagina. After the introduction of the anterior speculum the tube was grasped near the right uterine horn by a pair of ovarian forceps, and, by a succession of these and by manipulation of the fingers of the right hand, the tube, which was no larger than the thumb, was brought into the field, and three chromic catgut sutures were firmly applied about the ligamentum infundibulo pelvicum. The tube was ligated along the mesosalpinx, but the ovary was not disturbed. The hemtocele was as large as a child's head and a posterior vaginal incision was made on completion of the operation for drainage.

The second case was also a young woman, 22 years of age, who had had one child three years previous to her admission to the hospital. Two and one-half years before she had begun to complain of cramp-like attacks in the right iliac region occurring once in three or four months and lasting for two or three hours. These attacks had become more frequent and severe during the past year. The last menstruation had occurred a little more than four weeks before admission. Colostrum was present in the breasts, but no masses were felt in the abdomen. The cervix was small and soft and the uterus of the fundus was indistinctly felt forward. A definite diagnosis was made under anesthesia and she was operated upon December 10. In this case the plica showed the typical blue shimmer which was such an important diagnostic feature in ectopic gestation. Incision of the plica verified the diagnosis as dark clots and dark fluid poured out. As much of this as possible was removed with sponges. The uterus was turned so that the right horn was in the median line, and the fingers of the right hand enucleated the enlarged tube from the hematocele. The tube was brought into view by the application of clamps to the uterine end of the tube and to the ovarian ligament, after which a clamp was applied to the ligamentum infundibulo pelvicum. Then three ligatures were applied about the ligament. The tube was removed but the ovary was left behind.

Dr. Hiram Vineberg said that he thought this question had been threshed out long ago, and in Germany it was concluded that the best way to treat these cases of ectopic gestation was through an abdominal incision. They were dealing with a friable ligament and tube and one that was easily ruptured. The broad ligament would not stand for a great deal of of manipulation, and even in working through the abdominal route one should be very careful in tying off the ectopic tube and not to injure the broad ligament. A slight tear had been often overlooked and the patient bled to death from oozing from this tear in the broad ligament. In the majority of instances it was unnecessary to sacrifice the ovary, and surely it was more easy to save the ovary when the tube had to be removed when operating through the abdominal route. The vaginal route was of service when the patient was very stout, the symptoms not very definite and the local findings negative. But here all that was necessary was to make a small transverse incision posteriorly, in the fold, revealed by pushing the cervix toward the sacrum and in less than a minute one could ascertain whether there was free bleeding in the peritoneal cavity.

Dr. Herman J. Boldt said that there were some cases of extrauterine pregnancy in which it seemed desirable to do the vaginal operation, particularly in that class of cases in which one was uncertain of the diagnosis. It was an easy matter to make a vaginal opening for diagnostic purposes, but what was the use when the patients were in bed as long and there was more risk of secondary infection? Dr. Boldt thought the ground was well taken that the abdominal operation was to be preferred in most cases of ectopic gestation.

Dr. Bandler said he had always been conservative in the use of the term "total prolapse," reserving that phrase for cases extending several inches beyond the vulva. The expression "descensus of marked degree" meant that the cervix was visible beyond the vulva, but on pressure extended well beyond it. This was a case of marked descensus and was not the case that Dr. Boldt had in mind. In answer to Dr. Vineberg, Dr. Bandler said that there were very good reasons why the anterior route should be preferred to the posterior. When there was a large mass in the cul-de-sac they simply had to puncture it with a long pair of scissors, and the clotted blood flowed out into view if one was dealing with a hematocele. But in other cases where they were dealing principally with the products of conception still in the tube, or with very early cases, the posterior incision was of no value, because it bled rather freely, and when the peritoneal cavity was entered it was difficult to tell whether fresh blood was coming out from within the peritoneal cavity or from the edges of the incision. Again one could not look into the peritoneal cavity in order to ascertain what conditions existed there. None of these objections held good by the anterior path. There they made a simple transverse incision unusually combined with a longitudinal vaginal incision in the anterior fornix. The bladder was readily separated and in the several hundred cases which the speaker had done in this way he had never injured the bladder. When an anterior speculum was introduced the bladder was lifted up and the vesicouterine plica was beautifully exposed to view, and if blood was there the typical blue shimmer was seen and one needed to go no further, since the diagnosis had been made. The incisions were then closed and the operation was proceeded with by the abdominal route. If one was not sure of the diagnosis, or wished to go further, the peritoneum was picked up by forceps and was transversely incised and an anterior speculum was introduced into the peritoneal cavity and one could then see with the eye the intestine, omentum, both tubes, and both ovaries. One could introduce the finger and palpate them. Dr. Bandler did not advise the vaginal route for all cases, but he operated upon more than twice as many cases by that route than he did by the abdominal route. In early cases, or those in which the diagnosis was not clear, or where there was no active bleeding going on and where the vagina was roomy, this method was of extreme value either for diagnosis or for operation.

**Vaginal Hysterectomy, Hemisection of the Uterus, and the Author's Method of Preventing Cystocele.**—Dr. Bandler reported this case. The patient was 38 years of age and was operated upon for fibrosis uteri. After the peritoneum had been entered anteriorly by the "T"-shaped incision and after the posterior fornix had been transversely incised to enter the cul-de-sac of Douglas, the lateral walls of the cervix were exposed by pushing the vaginal mucosa upward, and two chromic ligatures were passed with the ligature carrier, one on either side, including the lower part of the broad ligament and the uterine arteries. The scissors cut between these two ligatures and the cervix until the uterine arteries were exposed, when each was tied off separately. Then the fundus of the uterus was delivered and the broad ligament was ligated from above downward by three chromic ligatures applied median to the ovary. No attention was paid to the tube and ovary unless they were diseased. The scissors then cut away the fundus from the broad ligaments down to the previously cut uterine arteries. The ligatures which thus embraced the entire broad ligament were then drawn out, so that the broad ligament stumps were in the vagina. Gauze was packed between them to keep the intestines and omentum out of the way and an anterior retractor kept the bladder out of the way. A heavy chromic suture was passed which united the vaginal flap of either side, the vaginal mucosa which had been removed from the lateral wall of the cervix and part of the vaginal mucosa of the posterior fornix, to the entire broad ligament of that side, the suture passing through the ligamentum ovarii or the upper part of the broad ligament, the peritoneum of the posterior wall of the broad ligament and the peritoneum of the cul-de-sac of Douglas. When this was tied on either side, each broad ligament was completely enveloped by vaginal mucosa, and the opening between the two sides had been narrowed. This opening was further narrowed by interrupted sutures applied along the posterior margin of the incision, and then the peritoneal cavity was packed with gauze, the removal of which was begun on the fifth or sixth day after the operation and completed by the tenth or twelfth day. The vagina was likewise packed with gauze. For two days there was considerable serosanguinous oozing.

**Vaginal Hysterectomy, Including Left Salpingo-Oophorectomy for Tuboovarian Abscess; Bisection of the Uterus; Clamp Method.**—Dr. Bandler reported this case. The patient was 44 years of age and had had four children, the last about twelve years ago. About ten years ago she had had an abortion. During the last six months she had had marked menorrhagia and during the last three months menorrhagia and metrorrhagia, with weakness, pain in the pelvis, and loss of weight. The uterus was larger than normal. With the use of the "T"-shaped incision the uterus was found adherent to the posterior pelvic wall and was pretty well surrounded by adhesions over the fundus. These were separated by the fingers and blunt dissection. A fibroid somewhat larger than a walnut was found in the anterior wall of the uterus. The uterus was divided in the median line, the right half being pushed into the peritoneal cavity, and the first two fingers of the left hand were used to separate from adhesions and to enucleate the left adnexa, consisting of a large tuboovarian mass surrounded by many adhesions. The mass was punctured to allow some of the contents to escape. On the right side only the uterus was removed, there being no marked changes in the adnexa. Clamps were applied on the left side to include the tuboovarian mass. The patient was operated upon November 26; the clamps were removed November 28 and the last gauze was removed December 12.

**Vaginal Hysterectomy, with Amputation of the Uterus at the Internal Os; Clamp Method.**—Dr. Bandler reported this case. The patient had had metrorrhagia which persisted for several years and which was due to several fibroids situated in the fundus of the uterus. With the aid of the "T"-shaped incision the bladder was separated from its contact with the cervix and uterus and from its relation with the anterior vaginal wall. By a posterior vaginal incision the cul-de-sac of Douglas was entered and two clamps were applied to unite the peritoneum with the edge of the vaginal incision. An anterior speculum was then introduced and the vesicouterine plica was widely incised. The anterior retractor was introduced into the peritoneal cavity and with the aid of successively applied volsella the uterus was brought into the vagina. Two broad ligament clamps were applied on the left side, and with the aid of scissors the uterus was separated almost to the level of the internal os. This area, owing to the angulation of the cervix produced by the first clamps that were applied from below, was a little removed from a clear view, and, in addition, a small fibroid was present at this point, so that a transverse incision was made at the level of the internal os, completely separating or amputating the fundus from the cervix. The right side was then clamped and separated down to this transverse cut, leaving the cervix still in the grasp of the two clamps first applied. The cervix was then removed. A few interrupted sutures diminished the size of the vaginal opening anteriorly and

posteriorly. A chromic catgut suture fastened each flap to the upper border of the broad ligament of its corresponding side. The clamps were removed at the end of forty-eight hours and the vaginal gauze in five days. The patient made a very safe recovery.

**Vaginal Hysterectomy, Morcellement, and Clamp Method; Bisection of the Uterus.**—Dr. BANDLER reported this case. The patient, a woman 55 years of age, had been under his care for three years for pronounced menorrhagia associated with pain on the right side. She was extremely obese, so that the contour of the uterus could not be made out. Bimanual examination showed on the right side, on a level with the cervical internal os, an intraligamentous fibroid the size of a tangerine. There was also another fibroid nearly as large just above the cul-de-sac of Douglas, another one anteriorly, and one or two others higher up. The patient had a rectocele and the vault of the vagina was not very wide, nor could the cervix be drawn far down. The vaginal operation was decided upon. The fibroid lying between the uterus and rectum made it impossible to enter the peritoneal cavity at the cul-de-sac of Douglas. This fibroid and the firmness of the ligamenta cardinalia, together with the intraligamentous fibroid of the right side, made it impossible to bring the uterus down. The cervix was then grasped by two Jacobson forceps on either side and split in two anteriorly and posteriorly up to the respective fibroids. The bladder was held out of the way and the splitting was continued anteriorly, the inner border of the two halves of the cervix being likewise grasped by Jacobson forceps. After enucleating the anterior fibroid the splitting of the posterior wall of the cervix was continued and a volsellum grasped the fibroid in the cul-de-sac. This was enucleated and then the anterior wall was attached. the splitting being continued up a little further. The two halves of the uterus were grasped and successive fibroids were enucleated. The intraligamentous fibroid on the right side was so close to the situation of the ureter and the uterine vessels that it was with difficulty enucleated by the finger and a blunt ended pair of scissors, the fibroid having been grasped by the volsellum. Every step of the enucleation had practically been accomplished with the aid of the eye. Then, by morcellement, the lateral walls of the uterus were resected, so that gradually the fundus came into view and more fibroids were enucleated. The splitting was continued over the posterior wall until the cutting ended in the longitudinal slit that had showing that the posterior fibroid had been retro- been made in the posterior wall of the cervix. The peritoneum of the cul-de-sac of Douglas was still intact, through which the intraligamentous fibroid had been removed, had attached to it several clamps which had been applied while the morcellement of the uterus was taking place. These were left *in situ*. The same condition was encountered on the left side. As much as possible of the uterine tissue along the lateral border was trimmed away. The opening in the peritoneum was packed with three strips of iodoform gauze and also the vagina. At the end of thirty-six hours the clamps were removed. The patient made a smooth recovery, with only slight symptoms of peritoneal irritation. One of the most annoying factors in the course of the operation was the very extensive rectocele which persisted in obtruding itself into the field of operation. The use of the clamps precluded the possibility of doing a perineoorrhaphy at the same time.

**Hydronephrosis, Containing Twelve Quarts, Removed Through an Anterior Incision: Recovery.**—Dr. JOHN VAN DOREN YOUNG reported this case, which was of unusual interest because of the size of the tumor. The patient had been suffering for fifteen years, although during this time she had continued at her work, that of a weaver. Her first symptoms, pain and severe gastrointestinal symptoms, were diagnosed as appendicitis. The tumor reached its present size five years ago. Recently the patient had suffered from disability due to the weight of the tumor. From the size and shape of the tumor mass, which entirely filled the abdomen, a diagnosis of large ovarian cyst was made. There were no symptoms referable to the kidney or bladder. At the operation, which was performed December 3, 1912, the entire intestinal tract was found displaced to the left. The uterus and adnexa were normal. Ten quarts of translucent amber fluid were withdrawn by means of a trocar. An incision was made in the posterior perineum and through the wall of the sac. The hand introduced into this cavity confirmed the diagnosis that the cyst was a hydronephrosis of the right kidney. The ureter and renal vessels were located and ligated, and the entire sac removed. It was estimated that two quarts more of fluid escaped during this process, making the estimated contents twelve quarts. The resultant cavity was drained through the lumbar region. The patient made an uneventful recovery. The diagnosis was confirmed by pathological examination.

**Depressed Fracture of the Acetabulum; Recovery; Presentation of Radiography.**—Dr. YOUNG reported this case. The fracture was occasioned by an automobile accident. An automobile weighing twenty-three hundred pounds fell on the patient, driving the acetabulum with the head of the femur inward three and one-half centimeters and upward two and one-half centimeters into the pelvic cavity. The patient had recovered and was now entirely well, having only a slight limp and no limitation of motion. Stereoscopic radiographs made by Dr. Lewald showed the bony displacement most clearly. The unusual feature of the case was that the joint was apparently uninjured, the deformity consisting of a breaking away of the ascetabulum and a displacement of the entire joint.

**Radiographs of a Sigmoid Loop, Causing Intermittent Symptoms.**—Dr. JOHN VAN DOREN YOUNG reported this case. The patient had suffered during her entire life from intestinal stasis, at times very severe. Her appendix had been removed. The gynecological examination was negative. The radiographs showed slight gastroptosis with moderate gastric retention. The transverse colon was slightly below the umbilicus. The radiograph taken after injection of the lower bowel with bismuth solution showed a complete sigmoid loop, unquestionably congenital in origin, extending above the umbilicus in front of and above the transverse colon. Dr. Young also exhibited a radiograph of a similar condition in an infant. He believed that the intestinal statis was due to this loop.

**Gastroptosis: Improvement After Medical Treatment. Should It Be Continued or Was Operation Indicated?**—Dr. YOUNG reported this case. The patient had had her appendix removed for persistent gastrointestinal symptoms without relief. She had been on diet exclusively of zoolak and raw eggs for eight months. Four months ago an ovarian cyst was removed, which from its location and size had pressed upon the rectum. After the operation the patient had been kept in the Trendelenburg posture for about three weeks. There had been no gain in wight until after the operation. The patient weighed 93½ pounds November 16, and January 11 98 pounds. There had been a marked improvement in her general condition and vitality. The treatment had consisted in diet, massage, the wearing of a belt, and assuming an exaggerated Trendelenburg and the Goldthwaite positions daily.

**Double Ovarian Papilloma.**—Dr. YOUNG reported this case. The patient was 45 years of age. She had been losing weight for two years, the total loss being 29 pounds. She had suffered for the same length of time from an irritable bladder, and from abdominal pains for the past six months. An operation was performed July 17, 1912. The specimens removed showed multiple cystic ovaries on both sides, with a papillomatous growth, the cysts with the papilloma making a mass in each specimen of four and one-half inches in diameter. The clinical diagnosis was confirmed by section which was also shown. The patient had made an uneventful recovery from the operation and was at present in good health.

Dr. HIRAM N. VINEBERG asked Dr. Young if the cyst was lobulated. On account of the enormous size of the cyst it had occurred to him that it might have been a cystic degeneration of the kidney, that variety known as polycystic degeneration, which usually affected both kidneys. Dr. Vineberg related a case of this nature which had come under his care in which, after removing a huge polycyst of the right kidney, it was found that the remaining kidney also presented polycystic degeneration, but the mass was only half the size of the one removed. The patient died about twelve days after the operation. In examining the removed specimen it was difficult to see how it could have contributed to the elimination of urea products, and yet it must have done so, judging from subsequent events.

Dr. HERMAN GRAD also reported a case of hydronephrosis in which, after removing a cyst of the right kidney, it was found that the left kidney had entirely contracted and that all the secretion of urine must have come from the diseased kidney. This patient died a few hours after the operation of uremia.

Dr. JOHN VAN DOREN YOUNG said that the case which he had reported was one of true hydronephrosis and not a case in which there were separate cysts.

**Ectopic Gestation with Unusual Features.**—Dr. HERMAN BOLDT reported this case. The patient was 33 years of age. She was seen in consultation for the purpose of

finding out whether or not she was pregnant. She had always menstruated regularly, but during the period she suffered from pain in the left iliac fossa. She had menstruated last on September 20. Since November 1 she had had slight spotting which bore no resemblance to blood. When seen on December 5, the uterus was slightly enlarged and softer than normal. There was no colostrum in the breasts. A diagnosis of pregnancy was made. When Dr. Boldt again saw the patient on December 30, she gave a history of having had a severe attack of pain and fainting ten days before. At no time was there any loss of blood. The history was clearly that of ectopic gestation and this was verified by the presence of a pelvic hematocele. She was removed to the Post-Graduate Hospital and on January 1 again complained of pain. The operation was done *per vaginam,* through the posterior cul-de-sac. After the evacuation of a moderate quantity of blood the introduced hand came into contact with the placenta on the left side; it was loosely adherent to intestines. Following the cord, a three months fetus was found behind the right broad ligament. The Fallopian tube was drawn upward with its fimbriæ loosely attached to the bowels. This accounted for the negative palpation findings at the first examination. The ampulla was somewhat dilated, but otherwise nothing abnormal was found which would induce one to remove the tube. Gauze drainage was used and the patient made an uneventful recovery. The woman had probably conceived during the latter part of September, but no subjective symptoms presented themselves until December 19; likewise, because of the dislocation of the tube, no objective symptom, except the moderate uterine change, was perceptible on December 5, although the woman was already about nine weeks pregnant. Dr. Boldt did not think that vaginal section was the method of choice in such cases, except under favorable circumstances, but the outcome was satisfactory in this instance.

**Myomatous Uterus, Complicated with Suppurating Ovarian Cyst on the Right Side, Tuboovarian Abscess on the Left, and Chronic Pelvic Peritonitis; Organic Heart Lesions.**—Dr. Herman J. Boldt reported this case. The patient, who was forty-five years of age, had been bleeding profusely for two months, but had declined examination. The lower part of the abdomen was filled by a tumor which was evidently adherent to all parts of the pelvis. It was clear from examination that a myofibromatous uterus was present, and that it was probably submucous was surmised from the profuseness of the flow. The error of diagnosis consisted in not recognizing the other pelvic complications. If they had been correctly diagnosed, the proper procedure would have been to first make a vaginal section and to empty the suppurating vaginal cyst *per vaginam* and also the large tuboovarian abscess on the left side. Spinal analgesia was resorted to because of the heart complications, but not being satisfactory nitrous oxide and oxygen were employed. It was still too soon to report the termination, but the patient was doing well despite the extensive peritoneal infection with pus.

**Submucous Myoma; Extreme Rigidity of the Pelvic Floor; Supravaginal Extirpation of the Uterus.**—Dr. Herman J. Boldt reported this case. The diagnosis of a submucous growth was verified at operation. The interesting feature was the unusual rigidity of the pelvic floor which together with the obesity of the patient made it inadvisable to do a pan-hysterectomy as had been intended.

**Cervical Myoma, in Anterior Wall of Cervix; Ovarian Cyst with Twisted Pedicle.**—Dr. Herman J. Boldt reported this case, which occurred in a patient forty-four years of age who had suffered an attack of severe pain a week before consulting Dr. Boldt. The pain continued for an hour and then there followed a period of relief of two hours, after which the pain again began and lasted three hours. This was followed by chills, and more or less pain had been present since that time. Menstruation had been regular, but very profuse. An examination of the abdomen disclosed a cystic tumor about eight inches in diameter which was not sensitive and could be moved by the palpating hands into different parts of the abdomen. In the lower abdomen a tumor was found which was readily diagnosed as a modified myofibromatous uterus. The cystic tumor was diagnosed as a cyst of the right ovary with a twisted pedicle, but the twisting not of such a degree as to cut off the circulation entirely from the tumor because it was non-adherent and there was no evidence of peritonitis. On operation the diagnosis so far as the ovarian tumor was concerned was correct. The myoma proved to be of the cervical variety, and was situated in the anterior wall of the cervix. The interesting feature, considering the location and size of the tumor, was that there were no bladder symptoms, while usually very small tumors caused vesical irritation if in this location. On the fifth day coils of intestine were protruding, and when the bandage was removed it was found that there had been no attempt at union of the abdominal walls, but that there was not the slightest evidence of infection. The wound was resutured and an uneventful recovery followed.

Dr. George Gray Ward, Jr., said that he had had two experiences in which there was complete failure of union of the abdominal wound and in the second of these this was to be expected as the patient was in the last stages of nephritis and her general condition was very poor. This patient had carcinoma of the uterus and an operation was the choice of the family. The abdominal wound opened on the sixth or seventh day after the operation. It was immediately resutured and the patient made a complete recovery and survived for six months, when she died of apoplexy.

Dr. Hiram Vineberg also recalled a case in which there was failure of union after an abdominal operation for carcinoma of the uterus. In this instance there was no sign of healing at the end of two weeks.

**Vaginal Shortening of the Uterosacral ligaments in Procidentia Uteri, with a Report of Ten Cases.**—Dr. Herman Grad presented this communication. After outlining the anatomy of the uterine supports, calling special attention to the importance of the pelvic fascia, and showing how they were affected in procidentia, he described an operation on the uterosacral ligaments, which was applicable in many cases of prolapsus uteri. This operation had been described by Dr. Henry Jellett of Dublin in a paper published in *Surgery, Gynecology, and Obstetrics,* August, 1911. In this paper Dr. Jellett said: "In general terms, the operation consists in exposing the uterosacral ligaments at their insertion into the uterus, in cutting them off the uterus, and in bringing them around in front and below the cervix, and at the same time shortening them as may be found necessary, so that they become again a support to that part of the uterus." Vaginal shortening of the uterosacral ligaments was an operation that claimed for itself a definite anatomical basis. Although the operation disturbed the normal anatomical relations, because it brought the ligaments in front of the cervix, it nevertheless accomplished just the condition that it was desirable to bring about in prolapse of the uterus Contrary to the views of the older anatomists, the uterosacral ligaments were not purely peritoneal folds, but had firm fibrous tissues as their structural integrity. These ligaments were capable of maintaining considerable pressure and weight. They were really part of the fascial structure, which was flattened out and included within itself all the muscular structure that made up the so-called pelvic diaphragm. Picturing the fascial sheet which extended from the bony structure of the pelvis and completely encircled the uterine surface, it would be readily seen that if this fascial sheet having become overstretched or torn in places was shortened by some operative procedure, it would of necessity raise those organs to which it was attached to a higher level. This was exactly what was being done by the so-called shortening of the uterosacral ligaments. These ligaments were not alone shortened, but the entire pelvic fascia as well. It was evident from the conflicting views regarding the structure of the uterosacral ligaments that histological studies were wanting on the ligaments of the uterine supports. If muscular fibers were present in the uterosacral ligaments they had escaped recognition on the part of the writer of the paper. Reasoning from analogy, he could not see why the uterosacral ligaments should contain muscular fibers. The surgical treatment of prolapse of the uterus had changed considerably during recent years and the operations that were performed to-day for the cure of this condition could be divided into two classes: 1. Those having in view the formation of adhesions of the uterus to other parts in such a way as to hold the organs in the pelvis, and prevent a prolapse out of the vagina. 2. Those operations which shortened the uterine supports and in that way kept the organ from prolapse. Both types found application in prolapse of the uterus. The multiplicity of operations that had been recommended for this condition simply attested the fact that there was no single operation applicable in every case. So far as the surgical aspect of procidentia uteri was concerned, these cases might also be divided into two classes: (1) Those that were past the menopause, and (2) those that were still in the menstrual period. For the cases that were past climacteric and had small uteri the so-called interposition operation was suitable. When

the uterus was enlarged this procedure was not applicable. In these cases a hysterectomy was called for and the broad ligaments were made to serve the purpose of a shelf upon which the bladder was made to rest and to which the vaginal tissues could be attached. In patients still menstruating, or in the child-bearing period, the operation of shortening the uterosacral ligaments was very applicable. The operation was performed as follows: A circular incision was made around the cervix which was met by a vertical one in the median line on the anterior wall of the vagina. The bladder was stripped up freely. The operator might shorten the round ligaments at the same time by entering the peritoneal cavity in front of the uterus. The round ligaments were seized and shortened, after which the peritoneum was closed in an appropriate manner, either anteriorly or not. The bladder having been stripped up the anterior wall, the latter was hemmed to the desired extent in order to repair the cystocele that had existed. Before the final closure of the incision in the anterior wall of the vagina search should be made for the so-called pelvic fascia. This fascia was stitched with a few chromic gut sutures, making a shelf for the bladder to rest upon. A search was now made for the uterosacral ligaments which could be readily found in the majority of cases by grasping the loose tissue behind the cervix. This tissue was severed from the cervix and by a little dissection the uterosacral ligaments were identified. Should this procedure for the ligaments by palpation. When found they could be loosened sufficiently to reach around the uterus and be stitched to the cervix in front. The uterosacral ligaments not result in finding the uterosacral ligaments, the peritoneum might be opened posteriorly and a search made ments having been prepared, the cervix was amputated, the degree of amputation depending upon the length of the cervix. The effect of attaching the uterosacral ligaments to the anterior of the cervix was to draw the cervix backward toward the sacrum; this effect was very apparent during the operation. The cervix was covered with a flap of vaginal tissue and the anterior wall of the vagina was closed in the usual manner. The case was then ready for the restoration of the perineum and cure of the rectocele. Dr. Grad then reported ten cases in which this operation had proved highly satisfactory and concluded that the Jellett operation of vaginal shortening of the uterosacral ligaments in procidentia uteri deserved a place among the carefully selected gynecological operations. It was based upon an indefinite anatomical basis, was devoid of danger, could be easily performed, was practical in application, and brought the desired results. It was an operation that could be combined with other operations, such as shortening of the round ligaments. Dr. Grad's experience with this procedure was so satisfactory that he said he could recommend it most highly.

Dr. Samuel Bandler said that Dr. Grad's use of the term "pelvic fascia" was a little confusing. What Dr. Grad had called pelvic fascia they were accustomed to call connective tissue. It was full of elastic fibers and generously distributed throughout the six connective tissue ligaments which were attached at the level of the internal os and about the cervix. This tissue was especially abundant in the lower part of the broad ligament, constituting at that point the ligamentum cardinale which was the most important structure in keeping the uterus in its normal position and holding it up in the pelvis. This pelvic connective tissue was very rich along the lateral borders of the cervix, and he believed that the uterosacral ligaments which Dr. Grad made use of in this operation included much of this ligamentum cardinale. He considered the high amputation of the cervix an important step of the operation and the way in which he covered the new external os with vaginal mucosa included within the needle's grasp these very structures, fastening them lateral to and anterior to the cervix. Any operation which served to lift the cervix up and back into the hollow of the sacrum was of great value because no operation could cure the patient unless the cervix assumed something of its natural location.

Dr. Samuel Jerome Druskin said that a similar operation had been originated by Dr. Wagner of Vienna and was first suggested in America by Watkins. At the Wertheim clinic the work was done by incising the anterior vaginal wall, then opening the peritoneum, getting hold of the fundus and pulling it down, and pushing the cervix back. This enabled the operator to get at the sacrouterine ligaments of the prolapsed uterus with ease. The broad ligament was then buttonholed on each side of and close to the uterus just above the parametrium. The sacrouterine ligaments were now cut close to their uterine attachment and drawn through the openings in the broad ligament, crossed on each side and fastened in front of the cervix. Any redundant ligament was resected. The lower part of the uterus now rested in a sort of hammock. The results were very good. The speaker laid stress on the importance of preserving the cervix.

## Books Received.

*The* Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

## Therapeutic Hints.

**Salvarsan in the Treatment of Vincent's Angina.**—J. Anglada and P. Réveille note that like other spirilloses Vincent's angina may be favorably affected by the use of salvarsan. They base their method of treatment upon the good results reported by Achard and Flandin in treating Vincent's angina by means of the local application of this drug. Because of its simplicity the authors prefer this method to the intravenous and intramuscular injections. The salvarsan may be applied directly to the lesions in powder form, or it may be mixed with glycerin and applied on a tampon. The applications are made twice a day. In from three to five days in most cases the cure is complete.—*Progrès Médical,* February 15, 1913.

**The Use of B-Imidazolylethylamine in Obstetrics.**—F. Jaeger reports that this drug is a valuable substitute for ergot in the stimulation of uterine contraction. If labor pains have begun, the administration of this drug makes them more effective and shortens the duration of labor. This compound occupies a position midway between ergot and pituitary extract. There is one important precaution to be noted in the use of β-imidazolylethylamine, namely, it should be administered only when the os is widely dilated, for otherwise it would cause a spasm of the cervix and retard labor. This drug is prepared from histidin by the splitting off of carbon dioxide. It directly stimulates smooth muscle.—*Zentralblatt für Gynäkologie,* February 22, 1913.

**The Treatment of Asthma in Children.**—T. R. C. Whipham states that in the case of infants, when the attack is of a bronchitic nature and induced by indigestion or a similar cause, a saline aperient is all that is usually required. For the relief of definite spasmodic attacks, inhalations of the fumes of niter paper or of the following are very effective:

℞ Stramon. fol. pulverat., ʒ ss.
Anis. fruct. pulverat.,
Potass. nitrat., aa ʒ ii.
Tabac. fol. pulverat., grs. v.

Antipyrin in doses of 3 to 5 grains at night is also useful in lessening the tendency to spasm. In the intervals between the attacks there should be administered a mixture containing potassium iodide, stramonium, and belladonna. If the paroxysm is severe, atropine may be injected hypodermically.

Any abnormalities in the nasopharynx should be attended to. Adenoids and enlarged tonsils should be removed, and cauterization of the nasal mucous membrane, especially if hyperesthetic, often causes improvement. Rickets should be treated on appropriate lines and the child's general health maintained by means of tonics. A change of climate may be necessary. A high, dry, and moderately warm place suits these patients best. An open air life and a carefully regulated diet are of eminent importance. —"The Medical Diseases of Children."

**Anesthesia of the Drum Membrane.**—N. R. Blegvad of Copenhagen has found that the following solution, applied on a tampon to the drum membrane, produces anesthesia of the latter in about twenty minutes:

℞ Cocaine hydrochloride, 1 gram.
Salicylic acid, 1 gram.
Alcohol, 2 grams.
Solution of suprarenal extract, 1 per cent, 20 drops.

### PERITONEAL ADHESIONS OF THE INSIDIOUS TOXIC GROUP.*

BY ROBERT T. MORRIS, M.D.,

NEW YORK.

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THIRTY years ago we gave scant consideration to the subject of peritoneal adhesions which follow acute inflammatory processes. A decade later, surgeons in different parts of the world were making a study of the importance of such adhesions, in their relation to post-inflammatory disturbances. Robinson of Chicago called attention to the frequency of occurrence of adhesions in the cecal region, sigmoid region, and gall-bladder region, in cases without history of acute inflammatory attack. He tried to show that they were caused in the cecal and sigmoid regions by traumatism produced by the action of the posas muscles. Robinson's theory we assume now to have been incorrect. Within the past decade we have come to hear much of Jackson's membrane, Lane's kink, and of the adhesions of the upper part of the abdomen which we may call briefly "attic adhesions." The time has arrived for a new perspective in relation to peritoneal adhesions, which are found to some degree in almost every adult on post-mortem examination.

At the outset we have to take into consideration various peritoneal defects which remain as the result of defective development of the embryo at the time when various organs are taking their respective permanent places. Such peritoneal defects, sometimes mistaken for adhesions, cause very little disturbance, for the reason that growing viscera adapt themselves pretty well to the situation. The group of defects which are now classified as Lane's kink and Jackson's membrane seem also to date back to embryonic life, and to consist in a later connective tissue hyperplasia in response to some irritation. There is contributory testimony favoring the idea of insidious irritation, in the presence of various adhesions associated with the colon, and with other structures in the vicinity of the pylorus and bile ducts.

In searching for a cause for this insidious irritating influence we have to take into the problem our recent knowledge concerning colonic bacteria, more than sixty species of which have been isolated. Many of these under normal circumstances appear to be symbiotic, playing a necessary part in digestive processes. The colonic bacteria which are harmless or useful under ordinary circumstances, and the colonic bacteria which are always injurious send an excess of toxins into the circulation to be metabolized, under conditions of present day civilization. All of the civilized nations of the world at this stage in our cultural period are now undergoing decline, with various degrees of rapidity. We find arrested development of the ductless glands and of other protective organs, in connection with other stigmata of physical decadence. This means a loss of normal protective efficiency against the toxins which are thrown into the circulation in excess. They are improperly metabolized, and cause harm directly—or indirectly through the proteolytic changes brought about by their presence.

It seems to be a tenable hypothesis that we are to have an increasing number of cases of Jackson's membrane, of Lane's kink, and of attic adhesions, for the reason that causes favoring insidious irritation of the body cells are increasing under the methods of life adopted by a gregarious species—*Homo sapiens*. It is perhaps not an untenable hypothesis to assume that Lane's kink and Jackson's membrane represent hyperplastic increase in connective tissue, something like Dupuytren's contraction of the palmar fascia; while the various peritoneal adhesions of insidious development seem to be due to toxic irritation of the endothelial group of cells. We have, then, demonstration of toxic irritation of connective tissue cells and of endothelial cells manifested in the ways characteristic of the two groups.

From the surgical point of view, one of the greatest new vistas for surgery is being opened. Surgery of the future will have very much to do with the results of insidious toxic irritation of abdominal structures.

The toxic impression is intensified in the presence of colonic stasis; colonic stasis is favored by the relaxation of peritoneal supports, common to a fairly large proportion of individuals in the community at the present time.

In most of our cases of colonic stasis we must at the outset of treatment of patients, obtain radiographs showing the position of the colon and stomach. The physician of the future will hardly dare begin treatment of many cases now believed to be purely medical until he has determined if colonic stasis is due to interference with motility, through abnormal positions of the abdominal viscera, or through the influence of peritoneal adhesions, and if these features are remediable through surgery.

One cannot briefly enumerate the diseases which have been held to be purely medical and which are now believed by many to have toxic origin—let us say, for instance, neuritis, migraine, epileptiform seizures, arteriosclerosis, and many of the psychoses. We do not know at the present time what proportion of such diseases belongs to a toxemia of colonic origin, but we do know that a certain number of them have this causal relationship, and it is for us now to find out the proportion. A sufficient number of cases of the sort mentioned, have cleared

*A paper read at the meeting of the New York County Medical Society, March 7, 1913.

up unexpectedly after surgery (which had for its object nothing more than the relief of intestinal stasis) to cause us to become cognizant of the vast dimensions of our new vista.

When the influence of colonic toxins first engaged the attention of the profession, crude surgical procedures were proposed—as might have been expected—and the proposal to remove the colon was seriously considered by some of the more radical students of the subject. The procedure was actually carried out, but with results which did not seem to justify its employment. The next step in advance consisted in suspending the stomach and colon in such a way as to give some relief from mechanical interference with colonic and gastric motility. This was often supplemented by partial excision of the colon, but the severity of the operation did not appeal to the general practitioner favorably. Now, surgeons are getting to agree upon the desirability of an operation which is done with such ease and rapidity that the patient has very little shock, and which suffices to place the patient in such condition that he is readily amenable to subsequent treatment aimed against intestinal putrefaction and fermentation, by the physician.

This operation consists in a simple short-circuiting of the colon. The ileum or cecum is placed against some convenient segment of the sigmoid colon, and the two structures held temporarily by traction sutures are quickly united in such a way that four or five feet of the offending colon are thrown out of commission. Sufficient storage room is left for fecal matter, but the large useless area of the colon is no longer able to turn into the circulation a harmful flood of toxins. The short-circuiting operation can be done through a comparatively small incision and with so little attendant shock that we sometimes see a patient reading a newspaper next morning in bed, and sitting out of bed in ten days.

There are many cases of Jackson's membrane, Lane's kink, and attic adhesions which will require more elaborate surgery, but the short-circuiting operation represents a refinement of later day surgery, which will be applicable as a sort of preliminary therapeutic resource, for the physician who wishes to gain easier control of a large group of patients presenting symptoms of chronic toxic origin.

616 Madison Avenue.

## THE PREVALENCE OF CATARRHAL DEAFNESS AND ITS ECONOMIC CONSIDERATION.*

By HAROLD HAYS, A.M., M.D.,

NEW YORK.

ASSISTANT SURGEON IN OTOLOGY, NEW YORK EYE AND EAR INFIRMARY, ETC.

In a recent conversation the question arose as to the difference in the mental attitude towards life of the deaf person and the blind person. The blind individual in the majority of instances looks at life cheerfully and is more or less contented with his fate, but the deaf individual, on the contrary, is usually morose and melancholy. A deaf man who was present at the time this conversation took place was asked if he could explain why this was, and he said the difference is this: "When you talk to a blind man you make him forget his troubles; when you talk to a deaf man you constantly remind him of them."

* Read before the N. Y. County Medical Society, March 7, 1913.

The number of cases of catarrhal deafness that we have seen both in the dispensary and in private practice up to the present time is appalling. I say "have seen" because I believe that these cases will occur less frequently in the future now that the otologist understands the importance of treating ear conditions in early childhood, and now that nasal troubles and throat obstructions, such as tonsils and adenoids, are removed early.

To indicate the frequency with which catarrhal deafness occurs it will be of interest to peruse the following figures taken from the reports of three of our large hospitals, the New York Eye and Ear Infirmary, the Manhattan Eye, Ear and Throat Hospital, and the Illinois Eye and Ear Infirmary.

In the year 1911 there were admitted to the ear service of the New York Eye and Ear Infirmary 14,606 cases (which included 3,752 nose and throat cases), making 10,854 ear cases. The number of cases suffering from middle ear disease was 6,561; 1,217 cases were suffering from wax in the canal, causing deafness, which was much relieved after cleaning out the canal. These comprised, however, 20 per cent. of the ear cases and about 10 per cent. of the total number of cases. There were 1,656 cases of O. M. C. C. (chronic catarrhal otitis media), forming 27 per cent. of the middle ear cases and 15 per cent. of the total number of cases. In the year 1912 there were 10,085 ear cases treated at the infirmary (2,625 nose and throat cases included), making 7,460 ear cases. There were 5,542 patients suffering from middle ear disease, of which 1,531, or 38 per cent., had O. M. C. C. There were 892 cases of cerumen, making 2,423 cases suffering with some form of deafness. O. M. C. C. cases comprised 17 per cent. of the total number of cases, and 20 per cent. of these complained of ear trouble.

In the year 1910 there were 7,913 cases at the Manhattan Eye, Ear and Throat Hospital, of which 5,381 were cases of middle ear disease. Of these there were 1,254 cases of cerumen, about 16 per cent. of the total number of cases. In 1911 at the same hospital there were 10,534 ear cases, of which 7,212 had trouble with the middle ear, or 68 per cent. of the ear cases. There were 2,824 O. M. C. C. cases, 27 per cent. of the total number, and 39 per cent. of the middle ear cases.

At the Illinois Charitable Eye and Ear Infirmary during the year 1909 there were 2,733 ear cases, of which 1,952 suffered from middle ear disease. There were 454 O. M. C. C. cases, 18 per cent. of the total number, and 23 per cent. of the middle ear cases. In 1910 there were 2,064 cases suffering from middle ear diseases. There were 456 O. M. C. C. cases, or 21 per cent. of the total number of cases.

We see by the above statistics that cases of catarrhal deafness form about 20 per cent. of the cases seen in our hospitals. Besides these we have to consider those patients suffering from cerumen or wax in the canal. These patients form about 10 to 15 per cent. of the total number of cases. The majority of these patients not only suffer from deafness as a result of the wax, but have some mild form of catarrh in the middle ear which becomes insidiously progressive unless something is done to relieve the condition.

We have here considered only the individual patient who comes to the hospital or office for the first time. Besides this we should also consider the return of the old patients and the proportion of these patients that suffer from catarrhal deafness.

In a clinic such as ours (Dr. Robert Lewis' Clinic) at the New York Eye and Ear Infirmary it is to be noted that over 60 per cent. of patients that return for treatment week after week belong to the class who are suffering from diminution in hearing and its accompaniment, tinnitus. Many of these patients are wage earners, and as such have a certain economic value, which is considerably diminished on account of this infirmity. The patient runs from one clinic to another seeking what little relief he can, and finding very little relief, if any. They are taken away from their work to come to the hospitals, and many of them cannot work at all. Some of them take their infirmity with an unusual stoicism and fortitude; others become neurasthenics and are a burden to themselves, to their family and to their friends.

There are many causes for catarrhal conditions of the ear. The majority start without any warning in early childhood, being a result of the various diseases of this period of life. Neglected ears are so common that it is an exception to find parents attending to this neglect unless they can notice some discharge or until the child becomes inattentive. Even where the period of childhood is outgrown without any notice being taken of any diminution in hearing, there are many dangers towards the organ of hearing in a city such as ours that are hard to overcome. Atmospheric changes form an important part, and the character of the patient's work has a great deal to do with the condition of hearing. "Slight deafness is widespread among jute workers, but other textile operatives may be afflicted in a similar degree," says Thomas Oliver in a book called "Dangerous Trades." This is due to the excessive noise of the looms. "It may be taken as a fact based upon experience that artisans who are exposed to such loud noises as are made in hammering rivets suffer from deafness. Boiler makers and riveters become deaf at an early age. Workers in sheet iron factories are sometimes similarly affected with deafness." These workers appear to hear far better while at their work, but it has lately been observed that they do not hear, but closely watch the lips of their fellow-employees until they become very proficient in lip reading.

In a very thorough article entitled "Occupational Diseases of the Ear, Nose and Throat" William Sohier Bryant says, "How widespread this subject is will be plain to you when you consider the occupations which are accompanied by dust, the escape of poisonous gases into the air, the escape of poisonous particles with the dust, continuous loud sounds, explosions and detonations, rapid changes of temperature, rapid changes of humidity, rapid changes of barometric pressure, wetting of the surface of the body, entrance of air in the external meatus, entrance of foreign bodies in the external auditory canal, blows about the head, entrance of pathogenic organisms, hydraulic pressure in external auditory canal or upper air tract."

He outlines the effects of sixty different occupations which all cause pathological conditions of these parts, chief among which are machinists, blacksmiths, barrel-makers, millers, engineers, stone workers, gun powder workers, firemen, pugilists, caisson workers, etc. He concludes his paper with the following apt remarks: "However, the great destructive force of the occupational diseases of the ear, nose and throat is appreciated when the number of those affected is considered. The preventive measures are to be sought by arousing public opinion to these evils and to their extended and vital importance. The danger in the case of every occupation should be recognized by law and should be minimized by law. When the public is sufficiently educated to appreciate the loss through these remediable hardships it will not be slow in demanding salutory legislation and in punishing by legal penalty and public approbrium. The special means of protection in every instance are very obvious."

The economic loss to the individual patient as a result of catarrhal deafness is seldom appreciated by the patient himself until his hearing has become so poor that very little can be done for him. The majority of these patients will spend any amount of time and very often much more money than they can afford to get relief after the condition is beyond help of repair. We have preached preventive measures in medicine for the last two decades, and every otologist I have no doubt has preached to individual patients the advisability of the prevention of deafness by using timely measures. The indication perhaps is more evident to the otologist than to the patient he is treating. How often do we spend hours telling these patients in our offices that they should have certain things done? We tell them to have nasal obstructions removed, to have abnormal growths from the throat taken care of, to come to us for one or two treatments every few months or at least for an examination, so that we can be sure that the condition is at least stationary or getting better. The warning signals are ever set by nature. A little feeling of fullness or a slight rumbling noise is thunder to warn us of the storm. A slight amount of treatment at such a time, before the hearing is actually impaired, while the catarrhal condition is still confined to the nasopharynx, will often cause enough relief to prevent deafness in later years.

But what is the use of all this preaching? Unfortunately, the patient will be skeptical. Unfortunately it is human for the majority of people to let their troubles come as they may. They will not come and be cured of what they haven't got even if the physician tells them they are sure to get it. Ever present before their minds is the question of whether the doctor is after their money or not. These patients take a great deal of time, and this time is often valuable to them as well as to the otologist, when they feel that they cannot afford either this time or the money. These are the patients who ten or twelve years later go from one doctor to another, handing out generous fees, hoping that the next new man will suggest something other than that the last old man gave them. We as otologists realize the futility of a great deal of this search, and yet there are few cases without some hope of slight relief which will lessen to some extent the burden of hardship.

Aside from the economic problem there is the vast social problem of the deaf and near deaf, the handicap of the hard of hearing in those pursuits and enjoyments of life that make life worth the living. The sound of the human voice, the conjuring of ideas from spoken words or sounds, the ability to appreciate many of the beauties of nature through the interpretation of sound, the independence of the individual as a concrete spirit are all lost, with the result that the deaf man "slinks into his skin" and drops out of social reckoning. The possibility of improving his thought is minimized. Lectures, the opera, the theater, the church, all of which form an important part of the social life, are no longer en-

joyed with spontaneity. Interpretation of the sounds emanating from the stage or platform interferes with the correlation of ideas. The man no longer enjoys his club life; the woman neglects her social teas. What is the result for such misfortune? The individual resides within himself, becomes too introspective, too self-absorbed, and his horizon is limited to the confines of his narrowing intellect. The blind man is not afflicted in this respect as much as the deaf man. The blind man can paint pictures; he can mentally visualize. Very few men can paint word pictures, for our training has not been such that our imagination has been stimulated to the extent of allowing us to present our minds with passing word thoughts. Memories of words are inaccurate; memories of sight leave a different impression that can always form a definite concept.

As Helen Keller says, "The problems of deafness are deeper and more complex and of much more importance than blindness. Deafness is a much more severe misfortune, for it means a loss of the most vital stimulus, the sound of the voice, that brings language, sets thoughts astir and keeps us in the intellectual company of man."

It has been within the experience of all of us to find certain patients who have had their life's journey made exceedingly hard because of their hearing defect. Many of these patients have grown into middle life, have married and have had children. They have always been able to support the family and have been able to put away a few dollars for their old age. Gradually the enemy has crept upon them. At first only a slight catarrh was present, then they felt a dullness in the ears, then they heard the noise of tinkling bells, of the roaring ocean or of the whistling of steam. Sometimes at this early stage they have consulted the family physician, who commits the costly error through gross ignorance of either avoiding the subject or else telling the patient to forget it. Gradually the hearing becomes less and less and the noise in the ears becomes worse and worse. Relief is sought of the specialist who honestly tells the patient that he has a catarrhal deafness which is bound to become worse unless he comes regularly for treatment once or twice a week over a period of months or years. The few visits that are made in the beginning are paid for grudgingly, and after the first month or so the patient gives up in despair, ignorant of the fact that the insidious process that has been going on for years cannot be cured in a few weeks. Another year passes, nothing having been done in the meanwhile, then another specialist is consulted. He gives the same advice and tries a similar treatment. So he goes on until he becomes hopelessly deaf. To him all physicians are scoundrels and money bleeders, and he sinks into that hopeless existence which makes life hardly worth the living. The position which he held a few years ago is weighed in the balance and, without any mercy, eventually his employer casts him off, and he joins the great army of the unemployed. He is the victim of his own ignorance and folly, but is hardly to be pitied in comparison with his wife and children. Their lot is far harder.

Five years ago I saw a patient at the New York Eye and Ear Infirmary who lost his hearing in the right ear in childhood. For some unknown reason the hearing in the left ear became lost entirely. The man had been an insurance agent who had been making $40 a week. He kept coming to the hospital week after week with no relief. Total nerve deafness had occurred in the left ear and he was forced to attempt to hear with the almost totally destroyed right ear. As an insurance agent he was absolutely useless. When I first saw him he had the free bearing of an ordinary independent American citizen. Within a few months he looked sick and disheartened, disheveled and frowsy. All pride was gone. I took pity upon him and treated him for over a year at the office. In an attempt to restore some hearing in his left ear I operated upon his nose, I opened up his eustachian tubes, I excised a portion of his ear drum, I cleaned out the right ear, but after a year of treatment he was very little better off.

Meanwhile his wife and children were practically starving. She finally managed to get a position that brought in a few dollars a week, while he stayed at home to care for two babies that they boarded for $10 a month. I tried hard to get him some clerical work, for he was an intelligent man, but no employer wanted a deaf man. I finally wrote a letter to the New York *Times* to see if they couldn't get him some work. This paper was kind enough to publish my letter in its advertising columns, with the result that one reply was received from a farmer up in the middle part of the State, saying that he would employ him as a farmhand if he would pay his own fare up to Syracuse. The man would have been of value as a bookkeeper, a letter writer, an envelope addresser, and in a hundred and one other positions, but no employer wanted a deaf man. I lost track of him for two years and then one Thanksgiving morning he dropped into my office and wished to present me with a five-dollar gold piece. He looked happier and apparently was contented on a salary of $9 a week that he earned in an electrical factory in the upper part of the city. I asked him how he managed to get the job, and he told me that there was so much noise in the factory when he went in to ask for employment that he could hear almost as well as the man who was talking to him, and therefore there was no suspicion of his being deaf. In other words, his peracusis in this instance served him a good purpose. Here was a case of a man in the prime of life, with the responsibility of a family, earning forty to fifty dollars a week, being reduced to pauperism within a few short months as a result of his hearing infirmity. The sadness of his case appeals to us, but what is to be done in numberless similar cases? I have a man under treatment now who had been making a salary of $30 a week, but when his hearing became practically destroyed he was told to accept half that sum or get out, although he could work just as well without hearing one word. Employers are unfair towards this class of people. It is a nuisance to them to employ a deaf man, and faithfulness of service for years avails the employee nothing once his economic integrity is lost. In the present stage of society we cannot blame the employer for not burdening himself with the incompetent. And yet every employer owes a certain duty to the community as well as to himself.

When we wish to reckon deafness from an economic standpoint there is a number of factors to consider. We have the problem of the individual, of his family, and of society as a whole. When a man who has been earning a fair salary loses his hearing he not only loses his wage, but oftentimes he becomes dependent on the community, on his friends or on his relatives. In many instances a man's family is left destitute. Unfortunately, we

have a peculiar condition to deal with, for we have found nothing thus far that can alleviate the condition sufficiently so that a man who has become deaf can again become a valuable economic factor. In these cases their faculties are as alert, their muscles are just as strong, their intellect is perhaps keener than before, and yet the individual is dropped from the working force, not because he is not as capable as he was before, but because his affliction is an inconvenience to his employer.

Our scientific and medical knowledge has increased to the stage where the blind can see and the lame can walk. It has not increased to the stage where the deaf can hear. The hard of sight can wear glasses and yet see, cataracts and visual opacities can be removed and the unfortunate can still live and work without being a curiosity. The lame man can be made to walk and often he can cover his infirmity enough to become a useful citizen. But what is being done and can be done for the man who is gradually losing his hearing? Mechanical appliances are not as yet perfected to the stage where a working man can wear one without being pointed out as a curiosity. In order to reckon the vast economic importance of this subject let us for a moment turn to some hypothetical figures. In one year, 1911, at two of our dispensaries there were approximately 5,000 cases of catarrhal deafness treated. Conservatively we may estimate that this is one-half the number of cases that are being treated in the city. Over half of these cases are females, but 75 per cent. belong to the wage-earning class. If we were to figure the average earning capacity of the individual at $10 a week how appalling is the loss of the annual income we see! Most of these patients are either thrown out of employment or else have to obtain a less lucrative occupation. If we reckon that their income is reduced 50 per cent. we find that they lose $25,000 a week, $100,000 a month or about a million dollars a year. Many of these patients apply to the charities. They must be maintained in one way or another; they must live and they must eat. Taking into consideration the money given by these charities, the amount of time spent in dispensaries, and the expense of hospitals for the relief of this condition, we can justly suppose that the ultimate cost for these 5,000 people amounts to at least from two to three million dollars a year.

What can be done for this class of individuals? At the present time the question has been thought of but little. Associations for the welfare of the deaf, outside of those institutions which care for deaf mutes, have been very few. St. Ann's Parish has established a club house for deaf mutes called the Gallaudet House. This institution aims to encourage social intercourse among its members, arranges religious services, and finds employment for some of its members.

Within the past two years the Society for the Welfare of the Jewish Deaf has been formed. It also maintains an employment agency. In answer to a letter of mine the Rev. Dr. Elzas, the secretary, states that during ten months they handled seventy-five individual cases. The fact that stood out prominently was the terrible handicap that the deaf man has in his struggle for a living. As a rule, no employer wants him, and when employed the employer is always glad to get rid of him. The objects of the society are as follows: (1) It is striving to ascertain the trades for which the various grades of the deaf are best fitted. (2) How the industrial department in the institution for the deaf can best prepare their pupils for the work that is to make them self-supporting. (3) What to do with the uneducated and unskilled deaf—a difficult problem, which will probably result in an establishment of some small factory such as broom or rag carpet factory. (4) The society is prepared to have any intelligent deaf man taught a suitable trade and to support him while learning. (5) It finds employment for those out of work and seeks to improve the industrial condition of those who are employed.

But of course this institution deals only with deaf mutes. I have no doubt that in time the scope can be increased so that they will include that most worthy class of individuals to whom we are referring in this paper. Oftentimes these institutions have to deal with a demoralized or an unmoralized class of people. Many of these deaf mutes think themselves as good or even better than their employers, and friction constantly occurs. They appreciate very little what is being done for them and consider that society owes them some debt. Such is not the case with the man who has become deaf later in life, and many of them are only too grateful to receive any assistance whatsoever in the way of obtaining employment. These patients, as I said before, often have families to support, and are willing to go to any length to make both ends meet.

In order to get some information as to what was being done in certain industries with regard to employees who have become deaf as a result of their work, I wrote letters to the New York Central Railroad, the International Brotherhood of Teamsters, the Metropolitan Street Railway Company, and the Bureau of Commerce and Labor at Washington. The railroads answered that they did nothing; the labor union did not answer at all; the Bureau of Commerce and Labor knew nothing about the subject. As we have seen, many trades are responsible for the deafness of their employees, and it seems to me that something should be done either by the Bureau of Commerce and Labor, by the labor unions, or by a special clause in the employer's liability act to further the interests of those who become disabled in this way. Riveters, boilermakers, caisson workers, workers in electrical shops, workers at looms, etc., are all susceptible to so-called catarrhal deafness. Although many of these employees go into these trades with their eyes (and we may say ears) wide open, yet they themselves are not entirely responsible for their own folly, for in many instances these people are unable to earn their livings in any other way. Some form of industrial insurance should also be issued and given these employees so that they may have some slight surety against their forthcoming infirmity.

There are numerous classes of employment open to the deaf man. Among them are book cataloguing, book keeping, envelope addressing, watchmaking, jewelry repairing of all kinds, clothing cutters, tailors, hat makers, and various operatives in industrial concerns; and among the uneducated there are various sorts of manual labor which could be done as well by the deaf man, providing the prejudice of the employers could be overcome.

I believe we are humanitarians as well as physicians and that we should all be interested in the furthering of the welfare of any class of individuals who are handicapped in the battle of life. We should become instrumental in the formation of some general association which would tend to increase the responsibility of the employer in those

classes of trades which are liable to cause diminution in hearing. At the same time we could readily enlist the sympathy of our more wealthy and influential patients who are suffering from deafness, so that they would contribute toward a movement which would help eventually in the alleviation of the suffering of individuals having the same condition.

## A FEW INTERESTING CASES OF BONE LESIONS.

By WALTER W. GRIFFIN, M.D.,

NEW YORK.

ATTENDING SURGEON TO THE FRENCH HOSPITAL AND BELLEVUE COLLEGE DISPENSARIES.

In recent years the perfection of *x*-ray pictures and laboratory analyses has aided very materially in the differential diagnosis of bone lesions, so that, at present, in obscure cases the more radical method of sectioning for diagnosis can be obviated in many of these cases. Still bone lesions go on being treated blindly, without a diagnosis; hopeless prognoses are given and the patient drags along undiagnosed, uncured and uncared for through pure failure on the part of physicians to resort to the now ever ready and convenient aids to diagnosis, which are not at all obnoxious to the patient and await the simple thought of the physician.

A presentation of four such cases, interesting in their diagnosis will present some of the difficulties that the patient often presents to the man endeavoring to do them benefit but which through their sensitive natures they leave the physician to find out for himself.

Case I.—M. S., a girl fourteen years old, of Russian-Jewish parentage, born in the United States, came under my care in the surgical clinic of Bellevue Medical College. Parents are both living and healthy; two brothers and two sisters likewise are alive and in good health. No history or signs of syphilis in any of the family.

Fig. 1.—Case I, showing osteoperiostitis of the right radius and left ulna.

Personal History.—Child had measles when one year old; otherwise presented no facts of importance.

Present illness began November, 1911, when she says by slipping and falling against a door she received an abrasion of her right hand on the dorsum of the wrist, soon presenting itself in the form of four papules which enlarged, discharged pus and persistently refused to heal. At the same time as she had received the injury to her wrist she also

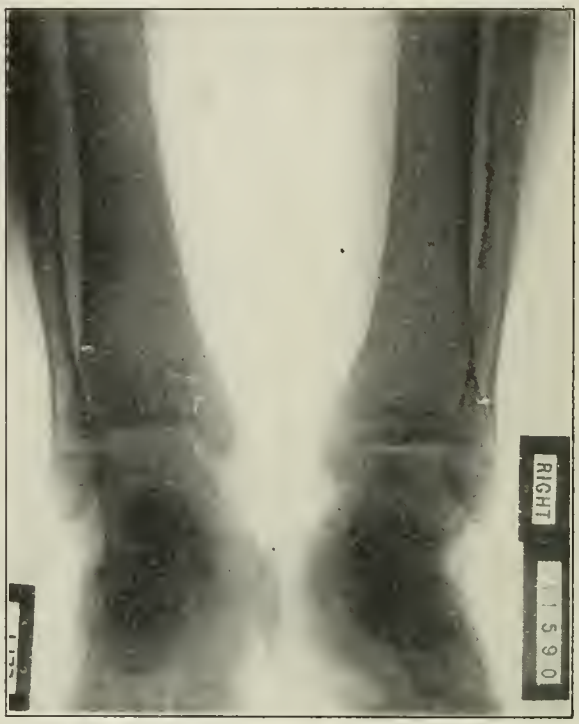

Fig. 2.—Case I, showing osteoperiostitis of the left tibia.

struck the left leg just above the ankle; after about two weeks this part became swollen, painful and inflamed; and then went on to form several pustules which discharged and likewise refused to heal. She applied for treatment to several of the lower east side dispensaries where her condition was treated without avail. Finally in the latter part of 1912 she appeared at Bellevue, where I saw her. Careful questioning failed to elicit any specific history either on the part of the patient or her parents. However, the girl's statement regarding the source of her injuries was varied. At one time she said her wrist condition was caused by a burn with hot water and her ankle to a fracture of the bone. At last she gave the above stated history of falling against a door, which she apparently thought most plausible because she has held to that statement firmly. Examination shows a young girl, well built and nourished for her age. Eyes, nose, ears, mouth, and throat in good condition. There were no stigmata of hereditary syphilis.

On the dorsum of the right wrist over the radius were four papules that had passed into the stage of ulceration. They were close together, had a bluish scarred areolar, undermined circular punched out borders and a soft spongy bleeding base with a discharge of a seropurulent nature. One of these papules was cavernous in its center and probing showed it extended to the radius. These lesions were not painful but were extremely tender.

On the inner side of the left leg at the fold of the flexed ankle was a mass of bluish brown pigmented scar tissue where apparently old lesions had healed only to break out anew in fresh places. In the center of this scar tissue were three ulcers, just such as I described on the wrist, and probing showed they extended to the tibia.

*X*-ray plates were made (Figs. 1 and 2) and they showed an osteoperiostitis of the right radius, the left ulna, and the left tibia. A Wassermann blood reaction proved, as I felt fairly certain it would, three plus positive. Under mixed treatment

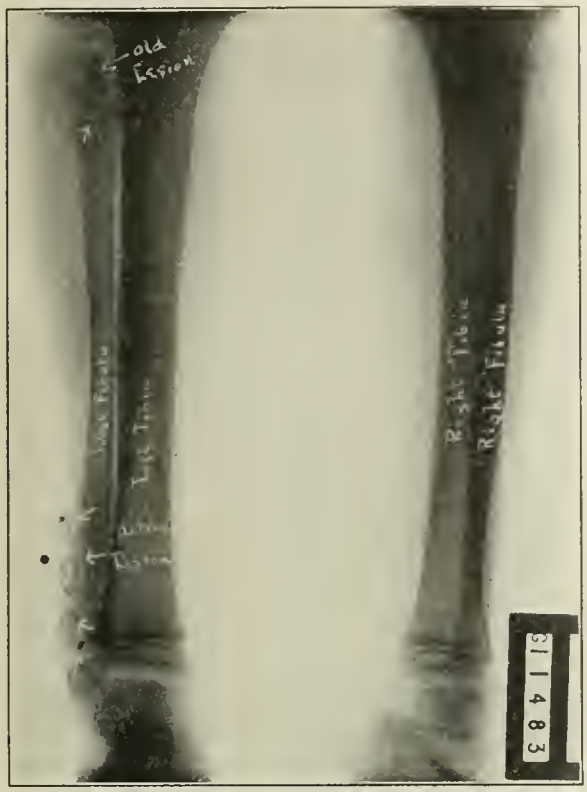

Fig. 3—Case II, showing the advanced osteoperiostitis in the upper and lower extremity of the left fibula.

and local dressings the ulcers promptly healed in the space of six weeks.

In this patient the local lesions had an appearance of specificity and I would have given the mercurial treatment without a Wassermann, but what an aid to a positive diagnosis was this three plus positive Wassermann!

Case II.—F. C., a boy of six, American parentage, saw me at Bellevue, February, 1913. I questioned the mother very carefully in regard to any specfic element in the family and she stoutly denied that any such condition ever existed. She had had no miscarriages or dead children.

Personal History.—Patent had intermittent malarial fever as a child but made a good recovery and has had no further attacks. Outside of an attack of measles, his personal history revealed no further facts. Present illness began one year and four months prior to his admission to Bellevue dispensary. The boy at that time fell and struck the lower part of his left tibia. One year later that part began to swell and formed a reddened soft mass, which was opened in a dispensary. The physicians at that institution treated the boy for four months and finally told the mother that the lesion was a tuberculosis of the bone and advised a radical cure or else to go elsewhere; the latter course appealed more strongly to the fond mother and she appeared at the surgical clinic of Bellevue.

During the treatment of the lower lesion a similar one appeared in the upper part of the leg; but this lesion scabbed over and apparently healed under treatment.

General examination availed no clinical signs of importance. There were no stigmata of hereditary syphilis.

Local Examination.—The healed lesion presented a thin cigarette paper bluish brown scar which lay over the upper end of the fibula. The *x*-ray at this point showed that the skin had healed over an apparently still active osteoperiostitis. The active lower lesion lay over the lower third of the fibula. It presented purely a canal leading to the bone. There were no signs of inflammation or were there any pigmentation, certainly a lesion diagnostic of nothing. Probing the sinus, it was found to lead to the bone.

An *x*-ray plate (Fig. 3) was made and it showed an osteoperiostitis of the upper and lower ends of the fibula with marked absorption of bone. A Wassermann blood reaction was now made and it was reported three plus positive. The boy was given mixed treatment and local dressings with the result that the lesions promptly healed.

After the blood examination I informed the mother that there was a "poisoning of the blood" in the boy which had been transmitted through some agency and asked her if she could not dig out something from her memory. Then came the anti-climax. She gave me a direct history of having contracted syphilis from her husband six years prior, at the time when she was seven months in the family way; her doctor had then informed her that it was too late an acquisition of the disease to transmit it to the child. After that, she had had one miscarriage and one dead born child.

This case shows again the value of the *x*-ray and the Wassermann. It also exemplifies the obstacles that patients will present just to keep their great skeleton locked in the closet of their memory, but syphilis picks the lock and gavorts about.

Case III.—P. M., an adult male, twenty-seven

Fig. 4.—Case III, showing new osseous formation about the embedded bone plate.

years old, born in Ireland, saw me in Bellevue during January, 1913. The family history presented no unusual facts.

Personal History.—Patient works as a kitchen helper, drinks moderately, smokes to the same de-

gree; bowels and kidneys functionating normally. He had measles and scarlet fever as a child and made a good recovery. Venereal diseases positively denied. Eight years previous he was operated upon for trachoma of both eyes and at present has a renewed attack.

Present illness began on June 17, 1911, when a gas engine machine weighing about two ton fell from a wagon, striking his right thigh; he was taken to a hospital, where a simple comminuted fracture of the femur was diagnosed. He lay in bed for one week until such time as the attendant swelling should subside, when he was anaesthetized, the thigh opened and the bone plated. The part healed slowly and after four months' time the patient left the hospital. At this time the right thigh was very much larger in circumference than the left. Apart from the swelling the right thigh was as serviceable as the left; free from pain and functionating perfectly. This satisfactory condition lasted for six months, when there came pain in the thigh at the seat of the fracture; two pustules appeared in the scar of operation. These opened and drained a seropurulent material for another six months, when the patient thought it best to seek surgical advice.

Examination.—Patient is a male of good frame, well built and nourished. Aside from the present attack of trachoma and the local thigh condition the physical examination revealed no abnormal facts.

Fig. 5.—Case III, another picture, the same as Fig. 4, taken at a different angle, showing screws and wire which the operator used to maintain the bone plate *in situ*.

Local examination of the right thigh showed it very much larger in circumference than the left. This swelling was fusiform, being largest at the seat of the old fracture, very hard on palpation and not tender. In the line of the operation scar were two sinuses which communicated after entering the flesh for a distance of two inches and formed a single channel which then led down to the bone for another two and one-half inches. From these openings there was a seropurulent discharge. The areolar about these sinuses was red and irritated, apparently by the discharge. Probing of these canals showed they led to the bone. The plates which had been applied at the operation could not be felt through these openings but the patient was certain they had not been removed. As a matter of having good habits in these cases, a Wassermann reaction was made and reported negative.

Fig. 6.—Case III, showing the leg after removal of the plate and after amputation.

*X*-ray pictures (Figs. 4 and 5) showed the plates still *in situ*, and embedded in a fusiform formation of new osseous growth, both of compact and cancellous nature. The tremendous extent of this new formation led to a doubt whether this was due purely to the long standing irritation of the plates, in which case the cure was simple, or whether there had been incited the formation of a malignant new growth, an osteosarcoma.

The patient was sent to a hospital. Here a pocket of sterile pus was found on the outer side of the femur by aspiration. An incision was made over the old scar, the plates found embedded in the new osseous formation and removed. At the same time a section of this tissue was removed for microscopical examination. The report showed that it was a giant and a small round-celled sarcoma. A disarticulation was now advised, which the patient promptly refused and was subsequently discharged from the hospital. However, in about a week the patient returned and the operation was performed.

Figs. 6 and 7, taken after the amputation, show the extent of the tumor formation and also that as far as the *x*-ray revealed local growth, the tumor

had been thoroughly excised, but further cellular or glandular involvement is feared and awaited. This case shows one of the dangers of leaving bone plates *in situ*. They should be applied only after the more common methods of treatment have failed,

Fig. 7.—Case III, showing the upper limit of the tumor formation revealed by the *x*-ray after amputation.

and once having served their purpose they should be removed. It also demonstrates the value of sectioning a suspicious mass for a pathological examination in order to make an early diagnosis which is so paramount in these cases since operation affords them the only hope of cure.

Case IV.—Was that of a man in middle life, of American birth, working as a traveling man, who was brought to Bellevue by his physician, fifty odd miles out in New Jersey, to have the opinion of a surgeon as regards an ulcer that the patient had had for six months and which instead of yielding to treatment, had been increasing in size. The family history was of negative importance.

Personal History.—Patient positively denied any venereal disease. The rest of his history was likewise of no importance as regards his present lesion. Present illness began six months prior as an apparently small abrasion of his left leg; this lesion soon enlarged and despite treatment has increased in size until at present it is about four inches in diameter.

. Examination revealed nothing outside of the present ulcer except an old pigmented scar high up on the left thigh which the patient remembered as a boil some years previous. The existing ulcer was situated on the middle third of his left leg lying over the tibia. The areolar was of a bluish pigmentation apparently due to a longstanding congestion at that point; the base was slightly deeper than the border, which was sloping, except at one part for about two inches of its circumference there seemed a tendency toward a circinate, punched out appearance. The granulations were large, pale, and avascular, with very slight seropurulent discharge. It is true that the patient had varicose veins, but the ulcer did not present the appearance of a varicose ulcer; in fact, it was just a plain ulcer and typical of no specific variety, except at that one punched out place, which might have resembled syphilis. The urine was examined and showed no albumin or sugar.

An *x*-ray plate was taken. This showed the tissue beneath the base of the ulcer formed a cup shaped mass of chronic inflammatory tissue which extended

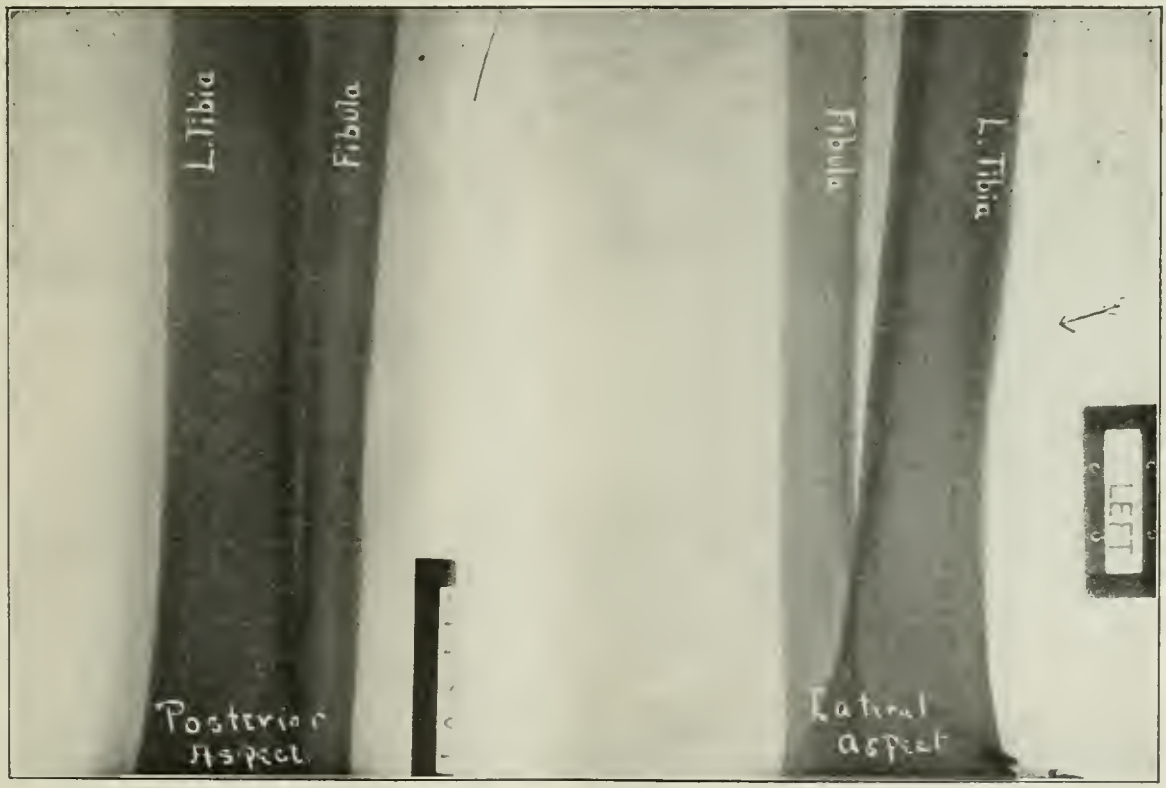

Fig. 8.—Case IV, showing local periostitis by downward infiltration of an ulcer. The small bullet-like spots are the shadows of phleboliths in the tissue of the ulcer.

to the bone and had incited a superficial periostitis. Unfortunately a Wassermann could not be made at that time and the patient lived too far to return and have it done.

Considering everything, the obstinate nature of the ulcer and the old scar, the physician was advised to put his patient on some form of mercury and increasing doses of potassium iodide, more or less as a therapeutic test; one might call it a "therapeutic Wassermann." Three weeks later the physician wrote to say that the ulcer was one-third healed and asked if there was anything further he could do.

In this case the diagnosis was doubtful, but I think the result after the therapeutic measures confirmed one of a syphilitic ulcer.

*Conclusions.*—(*a*) Remember the value of *x*-ray, Wassermann, and pathological sections in diagnosis.

(*b*) An *x*-ray showing a bone "mouse gnawed" is highly suspicious of a specific origin.

(*c*) Bone plates should be removed after they have served their purpose, since they are essentially a foreign body which incites irritation by their mere presence.

(*d*) Though highly lacking the element of science, still a therapeutic application of the "mixed treatment" certainly will do no harm and often will be found substantial evidence for or against a diagnosis of syphilis.

I wish to thank Dr. Lewald of the Edward Gibbs *X*-Ray Laboratories for his excellent pictures of these cases.

64 West Fifty-sixth Street.

## THE RESULTS OF TONSILLECTOMY.*

By BRYAN De FOREST SHEEDY, M.D.,

NEW YORK.

I DEEM it unnecessary before this gathering to spend much time on an introduction to my subject, as I dare say every man here has removed tonsils many times with what he and his patients considered satisfactory results. The text may seem ambiguous,

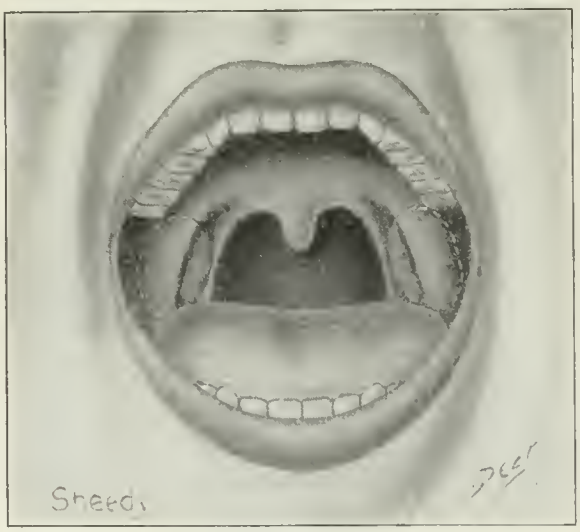

Fig. 1.

but in explanation would say that the apparent ambiguity was intentional as I desired that all present should discuss the subject from some particular angle, though my remarks shall be limited to a great extent to the throat results following the work. Not all have done tonsillectomies to the exclusion of the old-time tonsillotomy operation, and those who have done tonsillectomies may not

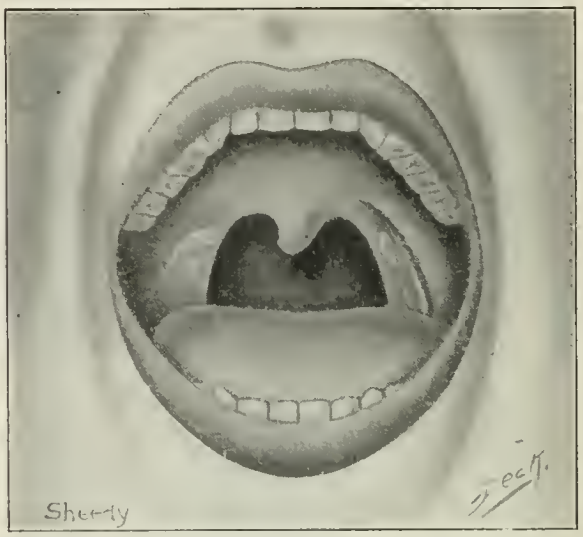

Fig. 2.

have observed the results of their work months after operation. I have noted the throat conditions in about fifty patients, as I found them from two to three months after operation, and will discuss those findings with you.

The results of tonsillectomy, so far as removing pathological tonsils is concerned, are, I believe, very much better than the results obtained from the old tonsillotomy procedure, and though we have many physical throat defects following tonsillectomy, the constitutional benefits derived from the procedure are, I believe, far greater and outweigh the drawbacks following the work. I also believe that some of the physical throat defects are due to the present customary method of removing the gland, so it is my intention at the end of this paper to digress from my text and point out to you a form of procedure which, I believe, promises to do away with some of the bad results obtained in tonsillectomy as it is now performed.

In order to emphasize one or two points I desire to make it may be advisable to refresh your memories in regard to the anatomical make-up of the gland and the tissues surrounding it. Whether the tonsil should be called a gland or the gland a tonsil or whether it should be designated simply as lymphoid tissue or given some other name will not concern us in this discussion. I will use the terms interchangeably and will consider the tonsil a mass of glandular tissue located between the anterior and posterior pillars, but quite independent of them when in a normal condition. The outer wall of the bed on which the tonsil rests is, as you know, made up of the superior constrictor of the pharynx over which there is a thin layer of connective tissue.

The gland, we are told, first appears at the fourth month of intrauterine life and reaches its fullest development at from five to seven years of age, at which time it begins to atrophy, and if it has not been diseased should have wholly disappeared by the time the child is fifteen years old. This gland is only a part of the lymphoid tissue derived from the hypoblast and it is important that we should keep this matter in mind, as too many physicians

*Read before the Medical Association of the Greater City of New York, February 17, 1913.

are inclined to consider disease of the faucial tonsils a local one without bearing in mind that the mass in the nasopharynx, which is called adenoids, or that found at the base of the tongue, described as the lingual tonsil, or the glandular tissue in the

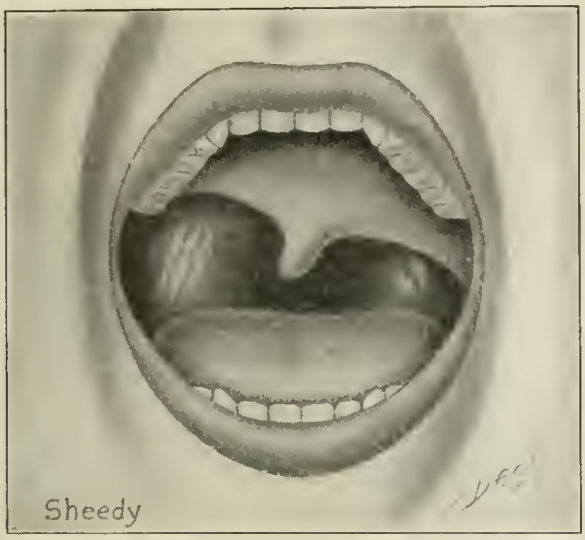

Fig. 3.

crypts of Morgagni, or the peptic glands of the stomach, or the lymphatic structures of the duodenum, or the mass going to form Pyer's patches, or that so often filling the appendix, are lymphoid structures and all derived from the hypoblast, so that where there is a tendency to hypertrophy and abnormality of one portion of the lymph structure, we should keep in mind the possibility of abnormality of all parts in which hypoblastic formations are found. This particular gland, we are told, is wholly covered by the plica tonsillaris before birth, but that shortly after birth the membrane disappears from that part of the gland afterward exposed in the oropharynx. The remainder of the gland is surrounded by a dense layer of connective tissue, generally described as the capsule. Therefore, the capsule extends all around the gland, excepting that portion opening into the throat. We find on the inner side of this capsule bands of connective tissue extending from one side of the capsule to the other and suspended on this connective tissue we find the glandular structures. Leading into the tonsil from the space over which there is no capsule are several openings, according to the size of the gland, which we call crypts or lacunæ, and we find that the mucous membrane covering the pharynx extends over the pillars and into these pockets and through its adherence to the surrounding structures, helps to hold the tonsil in position.

When we examine more carefully the tissues surrounding this gland we find that the anterior pillar is formed by the muscle, which runs from the soft palate to the base of the tongue, the palatoglossus muscle. The action of this muscle constricts the opening between the mouth and the pharynx and has to do with the position of the soft palate in the act of swallowing and talking. Frequently there are inflammatory adhesions found between this muscle and the tonsil. This muscle, where the tonsil is not very large, is rather thick and appears conspicuously through the mucous membrane covering it, in the act of gagging or when the tongue is brought forward. Where the gland has been hypertrophied for a great length of time we find this muscle, or in other words the anterior pillar, very thin, with only a few shreds of the former muscular tissue remaining.

The posterior pillar is also made up of a muscle which runs from the soft palate above to the pharyngeal wall behind, where a portion is inserted into the aponeurosis, while another, and the principal part, passes forward and is inserted into the thyroid cartilage. This muscle has much to do with properly locating the larynx during the act of singing. The combined action of the pillars on the right and the left side of the throat with the pad of Passavant, almost, if not completely, shuts off the mouth from the upper respiratory tract. The membrane of the pharynx extends over the posterior pillar the same as over the anterior pillar, holding the gland in position.

*Supratonsillar Fossa.*—The tonsil bed between the two pillars and above the superior surface of the tonsil, when in normal position, is generally described as the supratonsillar fossa and is covered by the same mucous membrane that covers the tonsil. In this space we find openings leading into the cellular tissues on which the tonsil rests and in which we have suppuration in cases of peritonsillar abscess. It is important at this point to remember that there are one or two crypts in the top of nearly every tonsil, which open into this space and which are frequently the cause of infectious material getting into the sinuses leading to the cellular tissue and causing peritonsillar abscess.

*Tonsil Bed.*—That portion of the tonsillar fossa actually occupied by the gland rests against the superior constrictor muscle of the pharynx, but between the muscle and the capsule is a layer of cellular tissue so that there is a layer of cellular tissue all around outside the capsule and between it and the muscles surrounding the tonsil. This is the tissue in which local anesthetics should be placed when the tonsil is removed under local anesthesia, so that the gland really rests on a mass of cellular tissue infiltrated with the solution used to bring about the anesthesia. As we look at the bed of the tonsil we find three large arteries leading to the gland. (1)

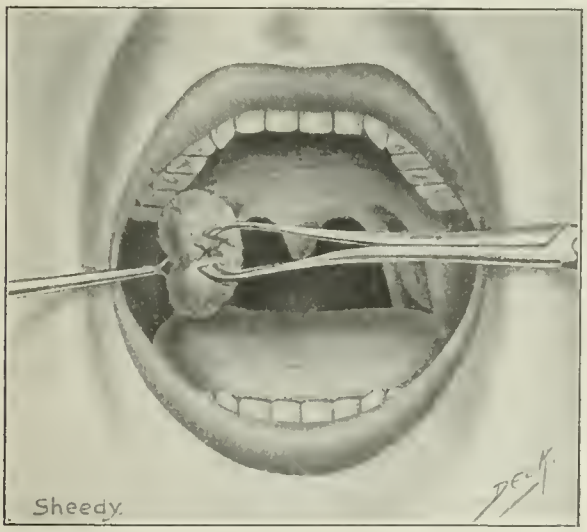

Fig. 4.

The tonsillar artery, a branch of the external maxillary; (2) the ascending pharyngeal, which is a branch of the external carotid; (3) the descending palatine, and several smaller branches; but the three enumerated are the ones we should have in mind in

dealing with hemorrhage. It is well to remember, too, that when you have a large hypertrophied tonsil all these blood vessels are enlarged and therefore many of the smaller vessels become very prominent. Without taking up too much time emphasizing the anatomic relationship of the tonsil, I want to impress upon you the outline of the pharyngomaxillary space, which lies behind and outside the tonsil and in which there is a large amount of cellular tissue and in which kidney-shaped space the blood vessels are found and in which we have the accumulated pus in peritonsillar abscess. The shape and location of this pharyngomaxillary space indicates why you should open your peritonsillar abscess at the point midway between the base of the uvula and the last molar tooth, where the space comes nearest the surface. The anatomic relationship between the blood vessels and this space also explains the serious hemorrhages that we frequently have in peritonsillar abscesses. As the nerves are found with the blood vessels you can readily appreciate that if this cellular tissue is infiltrated with a water solution we will have loss of pain in the removal of the tonsil.

With this review of the anatomy we are prepared to discuss the operation for the removal of the gland and without going too much into detail, would say that the aim in tonsillectomy has been to remove the gland with its capsule intact, and this has been accomplished either

(1) By taking hold of the gland with a pair of tonsil forceps and pulling the whole gland from its bed, dissecting away with sharp knives the mucous membrane and cellular tissue or

(2) By bluntly dissecting with the finger, and thereby tearing through the mucous membrane and the cellular tissue or

(3) By extracting the tonsil from its bed, incising through the mucous membrane and then passing the snare outside the capsule, thus removing the whole tonsil or

(4) By the Sluder operation.

The above procedures, or some modification of them, have been the customary methods for the removal of the tonsil.

Of the series of fifty patients, ages fourteen to forty, examined from two to three months after operation, in which some one of the above forms of surgical procedure was employed, I found deformed throats in more than 80 per cent. of the patients and not more than 20 per cent. of the patients had throats approaching the normal. In the ten patients with normal appearing throats the speaking and singing voice was perfectly natural from date of removal and they had no trouble of any kind following the operation. Of the forty remaining patients, 17 complained of speech defects for two or three weeks, 8 complained of speech and voice defects two months after operation, 2 practically lost the singing voice, while 13 said they could speak better and throats felt better after operation than before. About 5 per cent. complained of difficulty in using certain words and had nasal intonation.

The deformities following enucleation seem to follow one of two or three varieties. In the first variety the pillars on both sides seem to have disappeared, leaving a flattened surface where the tonsil formerly was and a much-narrowed opening into the nasopharynx.

In the second variety the pillars on both sides seem to have grown together, leaving but one pillar where there were formerly two, with the uvula pulled to one side or the other.

In the third variety the anterior pillar has wholly disappeared and a large amount of cicatricial tissue is deposited on the surface of the posterior pillar, altering its shape and function. In some of these cases the soft palate and uvula were pulled down to a very much lower position than normal, thus accounting for the nasal intonation complained of by some of the patients. In all the patients whose singing voice was affected the posterior pillar was very much out of the normal through the contraction of cicatricial tissue.

That you may get a better idea of the appearance of these throats I have had Mr. Deck, our medical artist, make composite drawings from a number of patients and these drawings I have the pleasure of showing you this evening. It would seem, therefore, that the question we should consider is "How to enucleate the tonsil with its capsule without incurring after-results that are unsatisfactory?" As a means to this end I have for some time been removing tonsils, both in my clinics and private work, in a way and by a procedure that I have not seen described in the books, but will endeavor to show you.

In adult patients I cocainize the surface of the tonsil with a 10 per cent. solution of cocaine and after cocainization has been accomplished I inject into the cellular tissue surrounding the capsule of the tonsil a 1½ per cent. solution of bisulphate of quinine. This makes the operation absolutely painless. In young children I use ether as a general anesthetic. The operation is done as follows:

With a tonsil tenaculum inserted as far as possible into the center of the gland, avoiding the capsule, I take hold of the bands of tissue extending from one side to the other and endeavor to invert the tonsil the same as you would invert a uterus by pulling on the cord of a retained placenta. Where the capsule is not too much contracted and where the gland has not become a solid mass of hypertrophied tissue and where the capsule is not bound down on all sides with bands of tissue left from old abscesses, on slight traction the tonsil will invert and after the same is completely inverted I pass the snare about it as shown on the chart and by slowly tightening the snare, taking from one to three minutes, the tonsil is removed without injury to the muscles, without pain, and without hemorrhage. I have employed this method during the past two years in a very large number of cases and yet am to have my first case with deformity following the procedure. After two years' experience and after familiarizing myself with the literature on the subject I am convinced that in the cases adapted for this operation, the proceeding outlined surpasses any operation heretofore known to me for the removal of tonsils.

## THE PATHOLOGY AND TREATMENT OF CALLOUS ULCER OF THE BLADDER.

By LEO BUERGER, M.D.,

NEW YORK.

ASSOCIATE GENITOURINARY SURGEON AND ASSOCIATE IN SURGICAL PATHOLOGY, MT. SINAI HOSPITAL; ATTENDING SURGEON, HARLEM HOSPITAL.

The very striking and remarkable result obtained recently in the treatment of two cases of callous ulcer of the bladder seems to me to be of sufficient interest to warrant reporting the cases in detail. By simple excision of the ulcers with a punch forceps through the operating cystoscope, two patients, both of whom had suffered most intense vesical

symptoms for more than a year, were completely cured.

In reviewing the literature on simple solitary ulcer of the bladder as well as what has been written on vesical ulceration in general, a striking diversity of

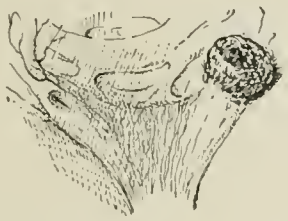

Fig. 1—Ulcer with exudate in Case 1. Cystoscopic picture.

opinion as to etiology, pathology and treatment is encountered. Indeed, a critical study of many of the published papers even arouses a suspicion of doubt as to the authenticity of the diagnosis in many of the cases. What with the larger experience gained of late years by diligent work with the cystoscope and what with the production of improved optical instruments, cystoscopists will more often be able to make a positive diagnosis of the existence of simple solitary ulcer of the bladder.

Thus it is interesting to note that Casper in his recent book on cystoscopy[1] makes no mention of operating or treating ulcers of the bladder with the cystoscope, although some thirty-five pages are devoted to the discussion of therapy through this instrument.

In the latest edition of the classical book of Nitze[2] this author refers to the condition of "simple ulcer of the bladder," but confesses to have very little experience with this lesion. In fact, he even goes so far as to throw some doubt upon the authenticity of the findings of such an authority as Fenwick. Therefore, this author at least had no operative experience with this condition.

In less than two years five cases of simple solitary ulcer of the bladder have come under my observation. Two of those recently observed belong to a type which, according to my own pathological studies, may truly be called "simple chronic callous ulcer of the bladder." It would take me too far from my theme were I to enter into a discussion of the various forms of simple solitary ulcer of the bladder and of the pathology and possible etiology. I shall therefore content myself with a consideration of the pathology and treatment of that form which may be designated as "chronic callous ulcer."

Two cases that had consulted me during the year 1911 were treated and cured by methods other than that which shall here be described. In one of these cases fulguration was successfully applied. In the other case repeated fulguration did not avail, and the ulcer finally healed under internal mercurial treatment. Neither one of these cases, however, belonged to the callous type with extensive involvement of the deeper tissues, and possibly the first one of them could have been healed by the application of caustics alone.

Where the process is deep-seated, where it has lasted for a long time, and where typical phosphatic encrustations have become deposited on the ulcerating surface with the usual train of symptoms—intense vesical tenesmus, dysuria, purulent urine and possibly contracted bladder—neither topical applications with silver nitrate nor cauterization by the fulguration method will have any beneficial effect. One of the cases in which fulguration was tried, well demonstrates the inefficacy of cautery methods in bringing about cicatrization and healing in such types of lesion.

A superficial study and cursory perusal of reported cases in the literature may give the impression that topical applications of silver nitrate can cure simple ulcer of the bladder. A critical review of the history of such cases and the cystoscopic findings will lead to the conclusion that such cases belong to the superficial variety of ulceration and that (as far as my own search in the literature goes) no case of deep-seated callous ulceration has been cured by topical application of medicaments alone.

Thus Armstrong[3] describes one case of ulceration about the size of a ten-cent piece, in a school boy 12 years of age, reporting a cure with irrigation of silver nitrate solution (1 per cent.) This ulcer was evidently not of the callous type, but a superficial defect.

Another such case is reported by Imbert[4], who, in an article entitled "Ulcères de la Vessie," purports to have cured an undoubted ulcer by irrigations of silver nitrate. He regards the case as one of simple solitary ulcer of the type described by Fenwick. There was no relation to trauma cystitis, tuberculosis or any demonstrable etiological factor. Here, too, the author was undoubtedly dealing with a simple superficial ulceration.

Those authors who have contributed most to the literature of solitary ulcers of the bladder, namely, Le Fur and Fenwick, are both emphatic in their belief that radical measures are absolutely necessary for the cure of the callous chronic variety of ulcer of the bladder. Although the work of Le Fur is based mainly on a study of the literature, the conclusions must be accepted as authoritative, for all available reports of cases up to the year 1901 had been carefully studied. This author says that in cases of simple chronic ulcer of the type under consideration, the methods of lavage and the use of silver nitrate cannot be regarded as reliable.

He quotes Albarran as saying that the solutions do not bathe the ulcers sufficiently when they are situated in certain regions of the bladder; but he also records observations of certain authors who have cured these cases with silver nitrate and lactic acid. He is strongly of the opinion that the operative methods of Nitze will prove of value as soon as methods are perfected for the purpose of applying strong solutions *in loco*, and when methods of cauterization and curettage of the ulcer have been properly devised. He says that he himself has had no experience with any of these procedures.

But when conservative treatment does not effect a cure, Le Fur recommends surgical intervention before the condition has advanced so far as to affect the general condition. Almost all other authors recommended the vaginal route in the case of

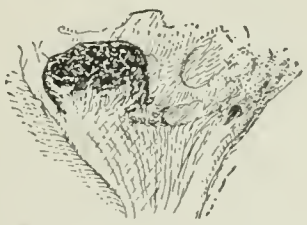

Fig. 2—Ulcer with exudate in Case II. Cystoscopic picture.

females, but the author thinks that this method does not do anything more than put the bladder at rest, and does not bring the interior of the bladder to view. Therefore the suprapubic route is preferable, in his opinion.

Hence as far as Le Fur's researches go, these ulcers do not seem to be cured by silver nitrate, and he rather doubts the efficacy of this method of treatment. Further, he sees hope in the employment of operative endovesical methods, although he

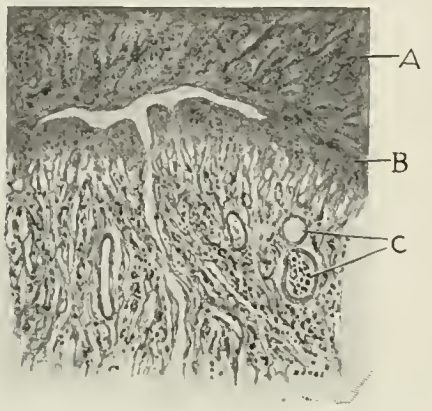

Fig. 3—Drawing showing microscopic section of callous ulcer; A, exudate on surface; B, zone of necrosis; C, inflammatory fibrotic tissue.

has had no experience with them; and finally he anticipates my own method inasmuch as he lays down the dictum that "resection (by the suprapubic route) is the best test that we have of the presence of a simple chronic ulcer, for if it fails to effect a cure, the ulcer may be regarded as of the malignant or tuberculous type."

Of all authors, perhaps Fenwick has contributed most of our knowledge of ulcer of the bladder. In his handbook of "Clinical Cystoscopy" (1904), he says that although some ulcers have healed spontaneously, it is unwise to trust to expectant methods. He believes that curettage and excision yield such good results that they should be undertaken as soon as possible.

*The Author's Treatment by Excision.*—With the operating cystoscope devised by the author and flexible forceps provided with cup-shaped jaws, it is an easy matter to attack practically any portion of the vesical mucous membrane. Difficulties are encountered only when we approach the vesical sphincter and the method in overcoming the obstacle in such cases will be described in a paper on operative cystoscopy. It will suffice here to say that the closed forceps is directed against the lesion in very much the same way as an ureteral catheter. The jaws are opened, the exudate covering the ulcer first removed with forceps, and then the bottom of the ulcer and borders are excised in as few bites as possible.

In the first of the cases which I shall report, the excision of the ulcer was performed for the purpose of diagnosis. The excision of suspected lesions in the bladder had been employed by me for a long time. The results were most gratifying, not only in cases of carcinoma of the bladder, carcinoma of the prostate, papilloma of the bladder, metastatic lesions in the bladder and follicular lesions, but also in doubtful cases of renal tuberculosis in which the pathological examination of excised portions of the suspected ureteral ostium often makes a positive diagnosis possible.[5]

A perusal of the following two histories will leave very little doubt as to the efficacy of the method of treatment, the rapidity of the cure as well as the failure of other procedures:

Case I.—E. H., forty-four years of age, married twenty-one years; seven children, was operated on, April 14, 1910, by Dr Lilienthal, for a tuberculous left kidney, the organ having been removed at that time. For a long time the patient was in the hospital in an extremely debilitated condition, and even after the nephrectomy wound had closed, severe urinary symptoms persisted. During the early part of 1912, as well as for a whole year preceding, the patient was suffering dire distress on account of urgency of micturition and desire to empty the bladder every fifteen minutes or half hour, the pain and ardor urinæ being present during the night as well as during the day.

During the first six months of the year 1912 she had received numerous treatments with the fulguration method for vesical ulceration. Although the cystoscopic findings seemed to indicate marked improvement in the vesical condition, the patient's symptoms were not at all ameliorated; so that in July, 1912, when, through the courtesy of Dr. Lilienthal, the patient was put in my charge, she complained of desire to urinate almost every half hour by night as well as by day.

In July, 1912, frequent cystoscopic examination showed the following picture: the right ureteral orifice was apparently normal, the vesical interior pale in places, congested in others, the most marked lesion being situated near the orifice of the left ureter in the posterior portion of the trigone. Here, arising from edematous angry red mucous membrane there was a grayish white tumor mass with a rather broad base and a flattened summit measuring possibly a centimeter or more in diameter. (Fig. 1). This mass appeared not unlike a necrotic papilloma, although to one who had seen lesions of this sort before, it made the unmistakable impression of a large exudate encrusted with salts, projecting from the base of a chronic ulcer. The diagnosis, therefore, was chronic indolent ulcer capped by a fungiform mass of exudate and salts.

When attempts were made to dislodge pieces of this projecting mass with a catheter, the mucous

Fig. 4—Photomicrograph of margin of ulcer; on the left, inflamed degenerate and hypertrophied mucous membrane; on the right, vascular inflammatory tissue.*

membrane bled profusely and it was impossible to separate a sufficient amount of it to bring into view the left ureteral orifice.

*I wish to thank Dr. F. S. Mandlebaum, Pathologist, Mt. Sinai Hospital, for the preparation of the photomicrograph.

During July and the early part of August, 1912, three treatments with the fulguration method were given without any improvement in the symptoms. On August 23 the whitish mass was still present with considerable edema and swelling in the juxtasphincteric portion of the trigone, particularly in the neighborhood of the left ureter and left half of the trigone, and the patient considered herself unimproved. A final attempt was made on August 23 with the fulguration method to thoroughly cauterize the affected area, several small portions having been previously detached by catheter and sent to the laboratory for histological examination and injection into guinea pigs.

The histological examination of the detached exudate showed the absence of any recognizable tissue and the presence of merely an amorphous mass stained deeply with hematoxylin—evidently an exudate containing lime deposits.

On August 27, 1912, some of this exudate was inoculated into guinea pigs and five weeks later the animals were killed, there being no evidence of tuberculosis.

The cystoscopic findings on September 23 did not vary very much from those previously described. The same edema and swelling of the distal portion of the trigone and the same tumor-like mass of exudate were found. Besides this, the infero lateral aspect of the right side of the juxtasphincteric region presented a number of follicular hypertrophies.

A month had elapsed since the last cautery treatment, with no improvement in the local condition and no improvement in the symptoms. Therefore through a period of three months, the local condition had not appreciably changed, in spite of repeated cauterization of the affected area.

*Excision of the Ulcer.*—In order to determine definitely by pathological examination of the affected area, whether we were dealing here with a tuberculous ulcer or not, it was decided to punch out not only the projecting mass of necrotic tissue, but also to remove as completely as possible the base of the ulcer. With the operating cystoscope and the largest cup-shaped punch forceps, it was a relatively easy matter on October 28, 1912, to remove the exudate completely as well as the floor and margin of the ulcer. A rather wide excision was made in order to obtain ample material for histological investigation. Immediately after the operation a firm coagulum formed over the affected area.

One week after the removal of the specimen from the bladder (Nov. 4) another cystoscopic examination was made. To our surprise, there was a marked improvement in the local condition, there being only a slightly hyperemic spot visible at the site of the former lesion. The patient, too, was emphatic in her statement as to the improvement in her general condition. The frequency of urination had diminished. She felt a great deal more comfortable and the act was no longer accompanied by pain. It was evident that the ulcerated area was now in the process of repair.

On November 11 the patient was again examined, and to our amazement the affected area was replaced by intact mucous membrane, somewhat paler than the neighboring mucosa, showing vessels radiating toward the site of the lesion. The picture was typical of that of a healed vesical ulceration. Corresponding to the change in the local condition, the patient's symptoms had almost disappeared, urination taking place every two or three hours during the day, every four to six hours during the night. The vesical ulceration was therefore regarded as completely cured.

On December 21, 1912, she was able to hold her urine for four hours and had to void only once a night. Vesical symptoms had completely disappeared and she considered herself cured. The catheterized specimen of urine was absolutely clear, and on microscopic examination of centrifuged specimens, only a very few pus cells could be detected.

*Summary.*—We were therefore dealing here with a case of intense vesical symptoms due to the presence of a chronic simple callous ulcer. This ulcer was not tuberculous and the etiology of the process could not be ascertained. However, prompt relief was obtained after excision through the operating cystoscope.

Case II.—Mrs. B. S., twenty-four years of age, married; three children, was referred to me by Dr. Kaufman on November 21, 1912, because of an intractable cystitis, severe pain on mucturition and ardor urinæ.

She had had three labors, the last pregnancy having terminated on the 19th of May, 1912. Her bladder symptoms began in November, 1911, about a year preceding, when she noted that she had to void more frequently than ever before, and that the act of urination was accompanied with burning and pain. At first she paid little attention to these symptoms until they became so severe toward the end of her pregnancy that she sought the advice of a physician who prescribed internal medication. After her confinement in May, 1912, the symptoms did not abate, but gradually became more severe, so that she had to urinate every hour or less during the day and frequently during the night. In August, 1912, about nine months after the onset of her illness, she sought the advice of Dr. K., who found that the urine contained a large amount of pus and some blood. She remained under treatment for almost four months, receiving frequent vesical irrigation with silver nitrate without improvement. The dysuria, painful micturition, and increased frequency persisted, so that finally she was compelled to void as often as every fifteen or thirty minutes during the day and every hour during the night. At times the urine seemed to contain clots of blood. Lately, the pain was so severe that she would "double up" during the act of micturition.

On November 21, 1912 cystoscopic examination was made. The whole trigone was markedly inflamed, the changes on the right side being more intense than on the left. The left ureter could be detected as a markedly swollen orifice imbedded in edematous mucous membrane. Not far removed from the left orifice occupying the middle and right cornu of the trigone there was a large whitish polypoid mass of exudate, the surface of which presented areas of brownish and blackish discoloration giving the impression of a tumor mass about the size of a hickory nut (Fig. 2). The right ureteral orifice could not be discerned, it being evidently hidden by the mass. Far back in the bas fond, situated somewhat to the right and the median line, there was a superficial defect in the mucous membrane, and not far removed from this in the posterior wall, another smaller abrasion. The rest of the bladder appeared to be pale and almost devoid of changes. The presumptive diagnosis after this examination was chronic ulcer involving the region of the right ureter and trigone, with intense

trigonitis, cystitis with some superficial defects and possibly right renal tuberculosis.

The urine contained a large amount of pus, numerous red blood cells, and cultures showed *Staphylococcus albus*. No tubercle bacilli could be found.

On December 6 she was again examined (without general anesthesia) the vesical changes being very much the same as those noticed at the last examination. Beside the cystitis which involved particularly the floor of the bladder, there were patchy areas in the right lateral wall with a superficial defect far back in the postero lateral wall. The left ureter was plainly visible, imbedded in swollen mucous membrane, but the region of the right orifice was occupied by a necrotic polypoid tumor-like mass not unlike that seen in Case I. A catheter was easily introduced into the left ureter, and then a second catheter blindly introduced in the neighborhood of the necrotic mass, the catheter slipping easily into the right ureter.

Most striking was the intense pain experienced by the patient when the catheter touched the bladder wall, indicating extreme irritability of the trigone.

Clear urine was obtained from both kidneys, the right side excreting 1.7 per cent. urea, the centrifuged specimen containing a few epithelial cells and a few white blood cells. The left ureteral specimens contained 2 per cent. urea, microscopic examination showing a very few red blood cells. Both specimens contained a very faint trace of albumin. The cultures from both sides were sterile. Indigocarmine appeared on both sides within fifteen minutes, indicating adequately functionating kidney.

The findings at this cystoscopy, therefore, were the absence of renal involvement, the presence of a chronic ulcer in front of the right ureteral orifice and cystitis with an area of erosion.

On December 8 a catheterized bladder specimen again showed numerous staphylococci (*Staphylococcus albus*) and an unidentified gram positive bacillus. No tubercle bacilli were found. A twenty-four-hour specimen also proved negative for tubercle bacilli.

*Excision of the Ulcer.*—With the diagnosis of chronic ulcer covered by a tumor-like exudate now well established, and with the striking curative result obtained in the previous case in mind, it was determined to excise the whole ulcer area and the polypoid mass, by means of the punch forceps through the operating cystoscope. Therefore, on December 9 the whitish polypoid mass was completely removed and the base of the ulcer punched out, both soft and hard pieces of tissue being obtained. The margins of the ulcer and a fairly large firm fibrous piece (undoubtedly representing the bottom of the ulcer) were identified both macroscopically and microscopically. All of these pieces were sent to the pathological laboratory for histological examination.

On the day following this procedure the patient already gave evidences of improvement as far as the urinary symptoms were concerned. Three days later the improvement was already marked, the patient being able to hold 10 oz. of urine without trouble. The urine obtained by catheter was almost clear, contained a few red blood cells and a few white blood cells.

On December 19, ten days after the excision of the ulcer, cystoscopic examination showed a complete absence of the ulcer. The right ureter was now distinctly visible, the trigone just in front of it being occupied by several small ecchymoses. The mucous membrane was swollen and the ulcer evidently in a process of rapid repair. The catheterized specimen of urine was perfectly clear and the patient regarded herself "well," voiding only three times during the day and not at all at night.

On January 3, 1913, twenty-five days after the excision of the ulcer, the patient reported her condition as follows: urination every five hours during the day and not at all during the night. There are absolutely no vesical symptoms.

Cystoscopy, January 10, 1913, revealed a practically normal bladder, there being no vestige of the ulcerated area. Pale mucous membrane in front of the right ureteral orifice was the sole indication of the former lesion. The patient considered herself "cured."

*Pathology of the Ulcer in Case I.*—The tissue removed in the first case did not differ materially from that obtained in Case II. A reference to Fig. 3 will show the general topography of this ulcer, the superficial exudate and deposit, the necrosis, the underlying inflammatory connective tissue. There was marked fibrosis at the floor of the ulcer and the periphery was made up of edematous vascular stroma, covered by swollen disintegrating mucous membrane. Except for the fact that here intense angiomatous formation was less marked than in the other case, and that the stroma was more edematous and cellular, no striking variation from the lesion in Case II could be found.

*Pathology of the Ulcer in Case II.*—Macroscopically, the excised tissue was composed of grayish white necrotic masses, soft tissue evidently containing mucous membrane, a few shreds undoubtedly from the ulcer itself and one large firm fibrous piece representing the bottom of the ulcer.

The necrotic material was composed of amorphous material, staining deeply with hematoxylin, together with aggregations of detritus and cellular elements, the component parts of a purulent exudate. The cellular elements were for the most part polynuclear leucocytes, a few swollen epithelial cells and some round cells.

Microscopic examination of those pieces, which evidently represented mucous membrane excised from the margin of the ulcer, revealed the following picture: (Fig. 4.) The mucous membrane is attenuated in many places whereas elsewhere it is apparently hypertrophied. Under the epithelium, the submucosa is seen to be composed for the most part of a multitude of fine vessels present in such large numbers as almost to suggest an angioma. Here and there the vessels are practically in contact, but, for the most part, they are separated by aggregations of round and plasma cells, and a scant number of polynuclear leucocytes. Where these vessels are most numerous, and where the cellular elements are in greatest abundance, there the epithelium seems to be most attenuated and to have undergone the greatest amount of degeneration. Thus the cells are swollen and distorted, and all evidences of a basal membrane are absent. Deeper in the tissue, the capillary vessels disappear and give way to larger dilated blood spaces with very thin walls, these spaces being encroached upon by aggregations of plasma cells and migrating leucocytes. Some of these blood spaces contain large numbers of leucocytes and evidences of an active inflammatory process, whereas others are only filled with blood.

Those portions of the mucous membrane which are seemingly hypertrophied present the mixed picture of thickened mucous membrane, exaggeration

of the crypts together with simultaneous destruction and disintegration of the epithelial clefts. Not only the surface epithelium, but also that which dips deep into the tissues is the seat of an intense inflammatory process, the crypts being filled with polynuclear leucocytes, swollen and disintegrating epithelial cells.

Therefore, the tissue in the neighborhood of the ulcer presents the picture of a chronic inflammatory process with enormous proliferation of vessels coupled with destruction of epithelium as well as hypertrophy of the epithelial nests.

Those sections which contain tissue both from the floor and from the margin of the ulcer may be described as presenting the following different types of change: First, the amorphous phosphatic and purulent exudate; second, the inflammatory tissue beneath this, and, third, the vascular tissue at the margin of the ulcer.

The same amorphous exudate previously described as being admixed with pus cells and detritus, can be seen firmly attached to the superficial layers of the bottom of the ulcer, the salts penetrating deeply into the tissues. Just beneath this deposit there is evident necrosis of tissue, and still deeper a layer of young connective tissue. Here, in the bottom of the ulcer, the capillaries are not so prominent as in the surrounding angiomatous tissue for the reason that this region has given way to the formation of dense fibrous tissue which has caused compression and obliteration of the vessels. Near the surface, however, of the ulcer, a few dilated capillaries with swollen endothelial cells containing numerous leucocytes are rather conspicuous, their presence being important in accounting for the tendency of these ulcers to bleed. The deeper layers are marked in places by the formation of fibrous tissue, although this is not so dense as to exclude small collections of plasma cells and leucocytes. This picture can be traced into the border of the ulcer, where a gradual transition into intensely vascular tissue occurs.

*Conclusions:*

1. Clinical, cystoscopic and pathological studies in two cases of vesical ulceration have conclusively shown that simple callous ulcer of the bladder can and does exist.

2. The clinical symptoms of this condition are intense dysuria, urgency, frequency of micturition with sanguineous and purulent urine. The manifestations become progressively more marked and take a chronic course.

3. The chronicity of this disease and the progressive impairment of vesical capacity speak strongly for the view that chronic cystitis and contracted bladder are often the sequelæ and outcome of solitary ulceration.

4. The region of the trigone seems to be the favorite site for the chronic indurated type of ulceration.

5. Although designated as simple, and often as solitary ulcer of the bladder, this condition may be accompanied by one or more superficial erosions of the mucous membrane, elsewhere in the bladder interior, lesions which are undoubtedly secondary to the intense cystitis accompanying the ulcer.

6. The most effective and rapid method of curing the disease as well as the simplest procedure is the excision of the ulcerated area by means of the author's operating cystoscope and punch forceps.

7. Less radical measures of treatment, such as cauterization with the actual cautery or fulguration, and silver nitrate irrigation are of no avail in this type of ulcer.

8. Histological examination in two cases has shown that the pathology of this condition is rather characteristic, there being a superficial deposit of urinary salts, a layer of necrosis and ulceration, and a stratum of newly formed connective tissue with active evidences of inflammation. The margin of the ulcer shows intensely vascular inflamed mucous membrane and submucosa.

9. In every case of chronic cystitis, particularly in women, where dysuria, urgency, and frequency of micturition are marked, a careful search should be made for this form of ulcer, for if it be present, it is more than likely that chronic cystitis, irritable and contracted bladder are secondary, and may be cured by the method advocated.

# SEXUAL DISORDERS ASSOCIATED WITH DISEASE OF THE NERVOUS SYSTEM;

## AND REMARKS ON PRESENT DAY SEXUAL PROBLEMS.*

By WILLIAM M. LESZYNSKY, M.D.,

NEW YORK.

ATTENDING NEUROLOGIST TO THE LEBANON HOSPITAL; CONSULTING NEUROLOGIST TO THE HARLEM HOSPITAL AND PEOPLE'S HOSPITAL.

We must all admit that the scientific study of the sexual sphere in the human economy has not been neglected. Not for a moment would I belittle its significance and importance. Of late, it is being dwelt upon with greater activity than ever, often, perhaps, in an ultrascientific manner, but always in an altruistic spirit. The public agitation resulting from the labors emanating from various kindred sources is truly remarkable and far-reaching. The plans elaborated for the awakening and enlightenment of the community regarding the anatomy and physiology of the human generative apparatus and the mechanism of reproduction; the prevention of conception; the suppression or control of prostitution; the prevention of venereal diseases, and the newer science of Eugenics are exciting popular interest.

Let me digress for a moment to mention incidentally how such topics often appeal to the masses and even to the average intelligent layman, unless carefully and judiciously presented. Twenty years ago, the first English translation of Krafft-Ebing's book entitled "Psychopathia Sexualis" was published in this country. It dealt with all generally recognized and unsuspected forms of sexual perversion, and had a larger sale among and was perused with more avidity by the laity than by earnest members of the medical profession. Of course, the majority of readers through lack of proper training failed to appreciate the true scientific value and spirit of the work, but were attracted through their morbid desire to indulge in so-called pornographic literature, and they discussed the subject accordingly *ad nauseam*.

In a recent book (1909) on "The Sexual Life of

*Read before the New York Physicians' Association, April, 1912, and the Bronx Medical Society, March 12, 1913.

our Time," by Iwan Bloch of Berlin, the American publishers state that the sale of the English translation shall be limited to the members of the legal and medical professions. The same was said of Krafft-Ebing's work, which was sold, however, without discrimination.

Let us always bear in mind, that, in common life, the rôle of the sex instinct is of fundamental importance. It is the only human instinct that can be compared with the instinct of self-preservation in respect to the profundity of its influence on the conduct of man.

Within the last decade, the sexual element in disorders of the nervous system has received more attention than heretofore. Thus, we have the advent of Freud's doctrine of psychoanalysis in the investigation of the psychoneuroses. In this work, the sexual factor in mental anomalies such as obsessions, phobias, anxiety, and the like, has been brought forward and emphasized as the fundamental and essential feature. He ascribes these conditions to "repressed psychical traumata" of sexual origin, arising during childhood or youth. Among Freud's numerous critics and opponents are many distinguished neurologists both at home and abroad, who, while admitting the value of his studies in psychology, are unwilling to accept many of his bizarre sexual theories.

The public instruction of adults and even school children in regard to sexual matters is a more recent innovation. It has seemed to me that the presentation of such information should be undertaken only in the most tactful and discriminating manner by specially trained physicians. It is unnecessary to teach more than can be properly assimilated. Whatever is taught, we must assure ourselves that it is not misunderstood. "More knowledge on the subject of sex than is required tends to a morbidity of imagination."

As a rule, the more thorough the elucidation the greater the misinterpretation. The dormant sexual instinct may thus be aroused in morbidly susceptible individuals, new mental complexes of a sexual character being formed, which may ultimately develop into various psychoneuroses.

In the case of children, however, individualization is absolutely essential as a precautionary measure against psychosexual curiosity and its baneful results. Hence, such teaching is impracticable and inexpedient in the public class-room, and cannot be safely relegated to pedagogical routine. Furthermore, the imparting of such knowledge to children should be the prerogative of instructed parents whenever possible.

Finally, the State has taken cognizance of the seriousness of sexual problems. Thus, we have recent legislative enactment legalizing the sterilization of male criminals and defectives, for the purpose of preventing their further propagation. This laudable idea has been carried out with such a degree of technical refinement, that only their *potentia generandi* is surgically obliterated, while their *potentia coeundi* is left unimpaired.

It has therefore occurred to me that under such conditions these individuals may ultimately, not only form a peculiar class by themselves, creating a new type of public prostitute, with an increasing demand for their innocuous sexual activity (so far as impregnation is concerned), but also serve as an additional element in the dissemination of venereal disease. Furthermore, such an operation would not prevent seduction or rape. We must also bear in mind that this legalized sterilization process would not deter the criminal from further depredations, which are so often fundamentally stimulated and encouraged by the incentive to gratify the mercenary demands of the woman with whom he is sexually associated. Besides, the *potentia generandi* can be restored by another simple surgical operation. Hence, would it not be better and more desirable to destroy completely all sexual power in such persons?

It has seemed to me, after careful investigation, that there is much misdirected energy expended in the public exploitation of what is termed "The Sexual Question." One of our most energetic and vehement preachers on sexual subjects has frequently stated that when such matters are publicly spoken of "a spade should be called a spade." In this way he thinks he can more successfully teach the public by dispensing with euphemistic language. In my opinion, such a plan should be materially modified and adapted to the character of the audience.

The awakening of the crude and undeveloped minds of young boys and girls by well-meant but unsuitable instruction in the physiology of human procreation and reproduction has often resulted in sexual precocity and an ignorant and wilful disregard of social conventionalities both in conversation and manner. It is a notorious and deplorable fact that so many of the popular novels of the present day, together with the stage, pander in such a large measure to the prurient tastes of the multitude, thus promoting the spread of morbid sexual proclivities.

Notwithstanding these and other antagonistic influences which are continually at work neutralizing the beneficial effects of all forms of uplifting methods, it may be safely said that the inhibition of gross sexual ideas, and the refinement, guidance, and control of the sexual instinct are still among the most significant evidences of advancing civilization.

In this paper another side of the question will be dealt with, namely, "Sexual Disorders Associated with Disease of the Nervous System."

From the standpoint of clinical neurology there is much to be said on this topic, but I shall refer only to some of the more frequent conditions that confront us. Excluding local affections of the genitourinary apparatus, chronic nephritis, diabetes, etc., symptoms referable to the bladder or sexual organs, are usually due to functional or organic disorders of the nervous system. Hence, in the absence of indications of local disease, all patients with genitourinary symptoms should be subjected to a neurological examination. It should always be borne in mind, that in neuropathic individuals slight sensory irritations are disproportionately magnified, this being particularly the case when they originate in the sexual organs.

When we are consulted by young men with all manner of neurasthenic and psychasthenic symptoms, and masturbation is admitted, it is our duty in the first place to instruct them regarding the dangers attendant upon continuance of the habit. In impressionable individuals one should be extremely cautious and not overdo the matter by dwelling upon the subject and exaggerating its seriousness. In some cases such a course will often increase the apprehension, for such patients usually have false notions already firmly established. To still further alarm them is a mistaken policy, often fraught with danger to their mentality.

It is not unusual for older unmarried neuropaths

to erroneously ascribe their symptoms to the remote results of masturbation practised during early youth. Their preposterous phobias are sometimes almost inconceivable. In quite a number of my patients over 40 years of age who were troubled by various obsessions, insomnia, etc., it required several months of treatment to successfully overcome the fixed and dominant idea that all of their symptoms were caused by masturbation discontinued before their sixteenth year.

In my experience, masturbation is more commonly a cause than a consequence of sexual neurasthenia. Occasional nocturnal pollution in psychoneurotic individuals is in itself of no serious moment. It is the misinterpretation of its significance, and the apprehension engendered and fostered by the perusal of quack literature, etc., that act as important contributory elements in the production and continuance of the symptoms.

The typical sexual neurasthenic is diffident and seclusive, exhibiting a lack of energy, and incapacity for sustained effort, his morbid introspection being colored by dominant thoughts of impending "lost manhood." He is on the borderland of insanity. It has been wisely said that "probably more unhappiness is caused by sexual impotence than by any other disease that affects mankind."

All experienced observers realize that in married life sexual impotence and sexual perversion are matters of momentous sociological and forensic importance. That impotence is often the secret groundwork of a seemingly mysterious origin of marital infelicity leading to legal separation or divorce is well known. On the other hand, the slightest disturbance or diminution of sexual power promptly demoralizes the worshiper of Venus and Priapus, and is soon followed by depressing thoughts portending impotency. This is particularly the case with bon-vivants, who commonly indulge in excesses of all kinds, and are more or less of a neurasthenic temperament. Not long ago a retired merchant seventy-eight years of age and of good physique and general health was sent to me for examination. For several months he had lost interest in his surroundings and suffered from mental depression, morbid anxiety and sleeplessness. It was soon discovered that the dominant obsession in this case was the fear of sexual impotence, which he said was the greatest misfortune that could befall him, even at his age. After several psychotherapeutic explanations he became reconciled to his physiological loss of function, and being resigned to the inevitable, he soon made a complete recovery from his mental symptoms.

Impotence in varying degree is at times an early manifestation of tabes (which is the commonest organic disease of the nervous system in which impotence is a familiar symptom). In many instances it is considered by the patient merely as one of the less important and unobtrusive phenomena. Nevertheless, the atypical tabetic may consult the physician in regard to diminution or loss of sexual power. Persistent attacks of priapism have also been observed in tabetics. It is just in these atypical forms of tabes wherein lieth a pitfall for the general practitioner as well as the genitourinary surgeon. It is a common occurrence for such patients to be treated for supposed spasmodic urethral stricture, or the organ stimulated by various measures, without recognition of the underlying cause. Incidentally, it may be mentioned that the restoration of the sexual activity in tabetics is not always advisable.

Owing to the prevalent traditional notion that incoordination in standing and walking is the pathognomonic symptom in all cases of tabes, its absence has often misled the physician into hastily excluding the disease without further investigation. As you all know, the abolition of the knee-jerk, and the lost reaction of the pupils to light, are among the characteristics and important objective signs. Only a few of the cardinal symptoms of the disease may be present, yet they may prove sufficient for a correct diagnosis. To the casual or ordinary observer, it would seem that testing for the knee-jerk and reaction of the pupils is a simple matter and requires no special training. But this is not the case. A methodical plan is necessary, in order to avoid erroneous deductions. Many years of observation and association with physicians have impressed me with the fact that these examinations are often either inaccurately or carelessly performed. On the one hand, is the danger of the erroneous assumption that the knee-jerk is abolished, and on the other, that the pupillary reaction to light is preserved.

Sexual excesses and congressus interruptus, or withdrawal (properly termed onanism), are common causes of impotence. The habitual practice of the latter at times produces a clinical picture simulating spastic paraplegia. Such patients have urethral hyperesthesia, aching and paresthesia with spasticity affecting both lower extremities, exaggerated knee-jerks, pseudo foot-clonus and general tremulousness, etc. Complete abstinence from sexual excitement and intercourse and general tonic treatment usually result in recovery within six or eight months.

It is very difficult, nay, almost impossible, to define accurately what may be considered excess in venery. Copulation for propagation may have its limitations so far as frequency of the act is concerned, but the absence of *potentia generandi*, or sterility in the wife is not a satisfactory excuse for over-indulgence. Just as in other matters, what might be considered moderation in one individual may be excess in another. It may be safely said, however, that sexual intercourse is excessive when it is practised with effort or followed by fatigue or exhaustion.

The claim that continence is a frequent or common cause of impotence, or that it is incompatible with good health, has not been satisfactorily proven. The idea is of foreign birth, having originated in European cities where sexual gratification flourishes as a fine art, and prostitution is officially recognized. Such a doctrine is not only fallacious, but its promulgation in this country is obviously dangerous.

The condition known as psychical impotence is of absorbing interest. As an independent affection, *i.e.* without any other involvement of the nervous system it is extremely rare. It may be classified in the same category with sexual hypochondriasis and neurasthenia.

I well remember the case of a healthy and vigorous young man brought to me by his father-in-law in the early period of my practice. In attempting the sexual consummation of his marriage he was repulsed by his wife who dreaded the ordeal. This was repeated many times. Several months later, when she was willing and anxious to submit, his *potentia coeundi* had entirely disappeared. He remained in this condition for several years. In another case seen about a year ago, a man forty years of age had for some time indulged in an extramatrimonial alliance. The woman then married a man of sixty-five, and she told the patient that her

husband was as strong sexually as a man of thirty. Subsequently, he endeavored several times to prove his superior or equal capability, but invariably found himself absolutely impotent through fear of failure. He has since remained impotent so far as this person is concerned, but continues normally his legitimate relations at home. Some of you may recall the classical case reported many years ago by Legrand du Saulle. The husband had never succeeded in coitus with his wife since marriage. After several years of unsuccessful treatment it was discovered that during his betrothal he had been in the habit of having sexual intercourse with his fiancée while she was completely dressed. He was then directed to undertake the act under similar circumstances and this plan proved successful.

Of course many other instances, possibly more remarkable, could be cited if time permitted. These histories have been briefly narrated for the purpose of illustrating and emphasizing the fact that the psychogenetic origin of this form of impotence varies with the mental attitude of the patient, being modified according to the diverse circumstances of association and environment.

Shock, fear, aversion, apprehension, worry, lack of self-confidence, mental abstraction, and superstition are the chief factors in the causation of psychical impotence.

In order to successfully manage patients with sexual disorders of nervous origin it is always necessary to closely investigate their status as to personal habits and domestic relations. In some cases, psychoanalytic methods often prove valuable in ascertaining the initial and persistent cause. The results of treatment by untrained and unskilled practitioners are usually unsatisfactory and at times disastrous. These supersensitive individuals find much relief in unburdening their mind to a physician of receptive temperament. Suitable psychotherapy is the essential feature. While other therapeutic procedures are indispensable, they must be considered of secondary importance. In impotency frequent repetition in attempts at coitus, or any form of sexual excitement, only increases the difficulty. Rest for several months is necessary.

Various ingenious mechanical devices have been utilized for the purpose of producing and maintaining erections in the impotent, but they are anything but curative.

In conclusion, permit me to state that the management of patients with neurotic sexual disorders requires discriminating judgment and much common sense. Haste and thoughtlessness in the prescription of so-called aphrodisiac drugs cannot be too strongly condemned. In the majority of cases such remedies are absolutely worthless. Unnecessary and meddlesome local treatment, in the presence of unrecognized organic disease of the central nervous system, can be avoided only by the acquisition and application of a useful amount of training in neurological diagnosis.

145 West 77th Street.

**Torticollis Following "Mumps" and Associated with Bilateral Cervical Ribs.**—L. H. McGavin reports the case of a girl, aged eleven, who three months previously had an attack of "mumps," which lasted a fortnight and caused much swelling, not only over both parotids but "round the back of the neck." During resolution the patient's head began to assume its present position, the face being tilted upwards and rotated to the left. A skiagram showed a well-marked but short cervical rib on both sides; these, however, give rise to no symptoms.—*Proceedings of the Royal Society of Medicine.*

# THE ACCURACY OF SYSTOLIC BLOOD-PRESSURE DETERMINATIONS BY VARIOUS METHODS, AND THE CLINICAL USE OF THE DIASTOLIC PRESSURE.

By LOGAN CLENDENING, M.D.

Kansas City, Mo

Instructor in Internal Medicine in the University of Kansas.

The auscultatory method of blood-pressure determination was introduced by Korotkow in 1905. He found that by placing a stethoscope over the brachial artery distal to the cuff of the blood-pressure apparatus a series of sounds could be heard as the pressure was released, and the pulse came through below. The succession of sounds has been divided into five phases: (1) A clear, tapping sound, which is agreed by all authors as indicating the systolic pressure; (2) a murmur makes its appearance, and either accompanies or replaces the tapping sound; (3) the murmur disappears and a clear sound persists; (4) the clear sound becomes dull. Warfield proves experimentally, and so far as I can judge conclusively, that the fourth phase corresponds to the diastolic pressure; (5) all sounds suddenly disappear.

These phases can in most cases be heard, and are usually well defined. The ordinary bell stethoscope is a better instrument for hearing them than the special instrument manufactured by the instrument houses for the purpose. In many individuals the various phases can not be sharply differentiated. The first phase, however, is always distinct.

Goodman and Howell believe that the length of the various phases measured in millimeters of mercury has some significance in judging the functional capacity of the heart. Dr. L. S. Milne and the writer have been interested in following their observations on a series of cases at the Bell Memorial Hospital. We have also tried to come to some conclusion as to the usefulness of diastolic pressure or pulse pressure in clinical practice, using the beginning of the fourth phase to indicate diastolic pressure. The number of cases we have observed has been too small up to the present time to have arrived at any conclusion. But in the course of them the writer has been interested in comparing the systolic pressure determined by the old digital method with the systolic pressure determined by the auscultatory method. It was thought that if it developed that there was a sufficient discrepancy in any large number of cases it might be feasible to recommend that one method be discarded for the other. A comparative set of readings was made upon one hundred cases; a mercury manometer and an ordinary bell-shaped stethoscope were used in each instance. Two possible sources of error could have entered into the calculations. One, that under the excitement of the manipulation the blood pressure of the patient would actually change, was partly obviated by changing the order of the readings so that on some patients the digital, on some patients the auscultatory reading was taken first. As a matter of fact, the readings were so close together that this error was ruled out in the face of the results. The other was the question of the personal equation—the fact that as one's opinions begin to crystallize about any procedure, that mental attitude is likely to influence the results. This was neutralized by the help of other individuals who took one reading while I took the other.

The average difference in the readings of 100 cases was 6.7 points-millimeters of mercury. The digital reading was lower than the auscultatory in 71 per cent. of the cases; the auscultatory was lower in 9 per cent. of the cases; the two readings are recorded the same in the remaining 21 per cent.—that is, there was certainly not more actual difference than one or two millimeters of mercury. Some readings showed a margin of difference as wide as 17, 14, 12, and one of 20 millimeters. These occurred in young subjects, not in the high readings.

A record of an average ten cases—11-20 in the series—is as follows:

| No. | Sex | Age | Note | Digital Reading | Auscultatory Reading | Diastolic Reading |
|---|---|---|---|---|---|---|
| 1 | M | 59 | Cardio vascular—renal cases Aortic regurgitation | 190 | 192 | 120 |
| 2 | M | 30 | Dyspepsia, Neurasthenia | 170 | 176 | 86 |
| 3 | F | 40 | Colloid goiter | 122 | 122 | 90 |
| 4 | M | 32 | Normal | 118 | 121 | 92 |
| 5 | M | 29 | Normal | 132 | 132 | 108 |
| 6 | F | 38 | Exophthalmic goiter | 144 | 150 | 100 |
| 7 | M | 26 | Normal | 131 | 140 | 108 |
| 8 | M | 43 | Fibroid phthisis | 132 | 138 | 117 |
| 9 | M | 19 | Asthma, possible pulmonary tuberculosis | 112 | 109 | 74 |
| 10 | F | 31 | Pleural effusion | 118 | 117 | 90 |

On the whole, then, it can hardly be said that the margin of difference between the two methods is large enough to be of any great moment. It is hardly conceivable that it could make much difference in any diagnostic puzzle. It is not necessary for life insurance companies to demand from their examiner anything but an ordinary digital reading. And this for at least one reason besides the actual small number of millimeters of difference in the two readings. That reason is that our interpretation of blood-pressure data is based upon readings made by the digital method. If we accepted the auscultatory method it might simply mean that we would put our upper and lower limits of the normal ten millimeters higher.

At the same time, the writer has found that with the increase of his experience he is coming to use the auscultatory method more and more. There are many cases in which the pulse is hard to feel after coming through a compression above. In these cases I have noticed that the mercury column begins to oscillate with the pulse beat some time before any full pulse can be felt. In these cases I am convinced the auscultatory method is nearer the accurate reading by the present standards of calculation.

In all these cases I have taken the reading of diastolic blood pressure, using the fourth phase to indicate this. While this particular series is too small to admit of judgment, I have not been impressed with its usefulness from the clinical standpoint. I cannot see that it tells us anything that we could not learn easier by a simpler method.

1025 Rialto Building.

**Bilateral Congenital Displacement of the Upper Ends of the Radius and Ulna.**—L. H. McGavin reports the case of a female child, aged 8 months, in which the deformity was noticed a fortnight after birth. Both arms were rotated internally, so that the thumbs pointed backward, and the palmar surfaces of the hands faced outward. Supination was possible only through a quarter of a circle with the elbows flexed. A skiagram showed transposition of the heads of the radius and ulna; the radius articulating with the trochlea and the ulna with the capitellum. There was no history of deformity in any of the other members of the family.—*Proceedings of the Royal Society of Medicine*

## Medicolegal Notes.

**Opinion Evidence.**—In a murder case a physician testifying for the State was permitted to say that the blow which caused the wound upon the deceased's head was a "severe" one. The witness had shown that he had been called to the relief of the deceased immediately after the injury, and that an examination disclosed a very serious fracture of the skull, which was verified by the post-mortem investigation. The fact that the blow must have been a severe one would be apparent to every juror of intelligence and the statement could not be prejudicial to the defendant.

The witness was also asked his opinion as to the character of the weapon or club that was used to produce the fracture found in the deceased's skull. He replied, "I believe a blunt or rounded, fairly heavy object—possibly like a whiffletree. That is the most common shape." It was held that the testimony was competent, the witness not having testified that a whiffletree had been used, but merely having used that instrument as an illustration.—State v. Baker, Iowa Supreme Court, 135 N. W., 1097.

**Implied Authority of Agent, etc., to Employ Physician.**—In an action for medical services it appeared that the minor son of the defendant had general permission from his father to operate his father's automobile. While using the machine for his own pleasure he, accidentally and without fault, ran over and injured a pedestrian, who was taken to a hospital. The superintendent telephoned for one of the plaintiffs, and he was driven to the hospital by the defendant's son, who informed him of the occurrence, and while at the hospital requested the doctor to give the injured boy every attention to save his life He did not attempt to contract on behalf of the defendant; nor did the doctors communicate with the defendant at any time before the completion of their services. When the injured boy was about to be discharged from the hospital the superintendent informed the defendant that the boy's mother was poor and would probably never be able to pay for the hospital charges, and requested the defendant to do something towards paying the bill. The defendant paid the hospital bill, informing the superintendent that he was not responsible. He then received a bill from the plaintiffs for their services. He had heard that doctors were attending the injured boy at the hospital, but did not know they were making a claim against him until he received the bill, which he refused to pay. It was held that the son was without authority to bind the father to pay the physicians. In order to authorize an employee to bind the employer to pay for physicians in attendance upon persons injured by the negligence of such servants the employment must have been of such nature that the act of the servant is reasonably within its scope. The cases of general superintendents of railway companies, general managers or agents, etc., go largely upon the corporate character of the employer, the usual practice pursued, and the great exigency which arises in railroad disasters, and the dangerous character of the business. A mere chauffeur in a town where the employer is known and can be readily reached by telephone, or by other speedy and certain means of communication, would not ordinarily possess such authority. Neither would an infant son using his father's automobile under like circumstances. Moreover, the stipulation entered into upon the trial that the boy in charge of the automobile was not to blame for the injuries cut away the groundwork from the implied authority raised from the desire to save the employer from damages caused by the negligence of the employee. Judgment for the plaintiffs was therefore reversed.—Habhegger v. King, Wisconsin Supreme Court, 135 N. W., 166.

**Liability of Corporation for Physician's Services.**—A physician was called to attend a boy who had been injured while working in a mill. He continued to attend the boy professionally for about two months and sent his bill to the company owning the mill. In an action for the amount of it the evidence showed that the company's bookkeeper had represented to the physician that the company would be responsible for his services and that this representation was known to the company's officers, and a reply letter written to the physician on receipt of his bill by the bookkeeper under the direction of the company's managing officer. It was held that the company was liable for the services, notwithstanding that the physician's employment had not been authorized at a meeting of its board of directors; the circumstances known to the company's officers being such as justified the physician in believing that the company would pay for his services.—Taylor v. C. M. Robertson Co., Connecticut Supreme Court of Errors, 83 Atl. 534.

## RACIAL PSYCHOPATHOLOGY.

It is beyond the skill of man to say when or where the present-day spirit of iconoclastic analysis and intellectual rebellion will show its next outcropping. Old institutions and ideas in science and medicine as well as in politics and society have gone by the board and new ideals and ideas have replaced them and been added to whatever shreds of the old may have survived the attack of a disbelieving age. In no field are these facts better exemplified than in the modern present-day attitude toward, and care of, insanity. As in many other medical fields so in insanity and mental defectiveness, the keynote now is prevention—prevention in the individual by avoidance of those habits and excesses of body and mind which predispose to mental instability, and prevention in the race by stopping the inheritance of mental taints. This latter is perhaps the most important object of our modern science of eugenics. It is a field which is being admirably developed by the National Committee for Mental Hygiene, and its allied and related societies and organizations.

In line with the intensive study of problems connected with preventing the reproduction of mental taints and psychopathic predispositions, is the study of racial and even in some cases national characteristics and attributes of mind. Racial psychology has never been satisfactorily studied, yet it is the basis of any inquiry into racial psychopathology. The subject matter of such an inquiry is found in the pathological phenomena which are characteristic of a race or which are found in it with any considerable frequency. Its object is to classify these phenomena and by pure inductive reasoning, assembling the data and then drawing hypothetical conclusions, and rules as a working basis, to trace the underlying laws and reasons for the phenomena observed. The practical function of such an inquiry in turn is to arrive at the means of remedying these pathological phenomena viewed from the racial standpoint. As ever anthropology and medicine have much common ground in this science of racial psychopathology, or rather the art of medicine is seriously concerned with it for the purpose of curing or preventing pathological mental conditions, whereas purely scientific medicine makes it a subject of anthropological research alone.

A recent number of the *Popular Science Monthly* (March, 1913) contains an article by Dr. J. G. Wilson entitled, "A Study in Jewish Psychopathology," in which the author ingeniously rather than ingenuously undertakes to prove two propositions, (1) that the Jews are a highly inbred and psychopathically inclined race, and (2) that the prevalence of mental affections among them is almost entirely due to heredity. His arguments are striking and thought-compelling, even though tinged with a fixed idea of anti-Semitism. He concludes that the excessive number of constitutional inferior insanities among the Jews is at least partially explained by the fact that centuries of inbreeding have produced a race with a paranoid make-up. The author proposes more careful avoidance of consanguineous marriage and the introduction of non-Jewish blood into the race as a solution of the problem. If his premises be accepted, his conclusion is sound and his remedy logical. But there is much to be said on both sides and the discussion must from the first be raised above the suspicion of prejudice or personality. Its true significance, and the reason for adverting to it here, is in illustration of the growing importance of a careful investigation into racial psychopathology as a valuable addition to our means of combating the prevalence and increase of mental disorders and defects.

The surgeons at Ellis Island know full well that no just examination of the mental status of an immigrant is possible without some understanding of his mental habits, his inherited characteristics, and his environmental relationships. No cut and dried rule of thumb can be applied to any two races with a successful result. The Binet measuring scale of intelligence is an admirable test for French school children but it is inapplicable to the child of the Servian or Macedonian peasant. The Pole and the Greek, the Arab, the Finn, the Lett, the Italian, the Basque, even the German, the Swede, the Jew, the Englishman, and the Frenchman must be tested mentally with some understanding of the typical mentality of each. Wilson contributed a new angle to the observation of Jewish racial psychopathology. Whether or not his particular views and conclusions are correct is of much less importance than that interest be stimulated in this new field. First steps have often to be retraced but only by taking them can further progress and further knowledge be obtained.

## FATIGUE AND EFFICIENCY.

Fatigue is generally attributable to the waste products formed during muscular action, not only in muscular tissue, but throughout the economy as well. The extract of fatigue muscle injected into animals induces pronounced languor; injecting extract of non-fatigued muscles gives no such result. Soldiers after an exhausting march are as arm tired as they are leg weary. The workman who does not rest adequately for his needs loses his energy, psychic as well as physical—the fagged brain is fully as unreliable as the fagged muscle; this is a consid-

eration which should vitally interest the employer, from an economic if not from a humane standpoint. The latter should comprehend—indeed is more and more coming to do so—that, as Lee says, "mankind at present can administer no food or drug that can push the wearied cells up the metabolic grade simultaneously with their descent, or quickly after the descent has ceased. Only the assimilation and detoxication that normally come with rest—and best, rest with sleep—are capable of adequate restoration of working power."

The best surety against accident during work is an alert, refreshed mind in a virile body; on the other hand, the sure predisposition to accident is an exhausted, run down, devitalized human machine. There is now no question of the relation between fatigue and accidents; in Europe (and especially in Germany where the number of industrial accidents has been reduced fifty per cent.) this relation has been scientifically noted for practically all forms of human activity. Bank clerks make most of their errors in the late afternoon; wherefore there is now early closing of these institutions, since bankers have found their employees' mistakes too expensive for the maintenance of longer hours. Every one now knows what dreadful calamity must be feared when railway men work too many hours through many days. As to druggists: to err (with perhaps fatal consequences) in the filling of a prescription is indeed human and hardly blameworthy in a clerk who must be attentively at his post almost two-thirds of the twenty-four hours. And when such daily exhaustion in any trade or occupation is extended into weeks, becoming more and more incapable of re-creation by rest, a total disability results. And this becomes a matter of especial economic importance in positions where experience is what the employer is largely paying for.

In a recent "Scientific Study of Fatigue and Efficiency," published by the Russell Sage Foundation, Miss Josephine Goldmark has emphasized the part played by overstrain and long hours in the breakdown of health and efficiency among working people; although she by no means disregards the baneful influence, in debasing vitality and producing illness, of poverty and low wages, dark and insanitary tenements, dirt, overcrowding, lack of privacy, bad food and worse cooking.

There are those who hold that shortened hours of labor give the workers just so much more opportunity for dissipation—that there is more leisure to go wrong when people live in wretched homes with only the streets and the saloon to go to for recreation (to be re-created in). But Miss Goldmark destroys such reasoning, not by means of theories and speculations, but by sympathetic deductions from facts. Where cynics have prophesied drunkenness and rowdyism through the leisure derived from the shortened hours of labor, a kind of regeneration has really taken place. "Workers have made extraordinary advance in physique and morals." The gradual emergence of the English mill operatives from the physical and moral degenerations into which they had sunk in the thirties of the last century, is not exceptional but typical. It is an humble chronicle but full of meaning to any reader who loves the fulness of human nature. Gardening, sewing out-of-doors summer evenings, evening schools in winter, time for "the endearing trivialities of human life"—these were some of the simple yet enduring things at which mill workers learned to spend their leisure. And there has been an increase in temperance, which need not be surprising when one grasps "the truth that among industrial workers the desire for drink has often sprung from sheer physical exhaustion."

## STATUS TO-DAY OF THE WORLD PLAGUES.

The United States through its Public Health Service, operating to a large extent through the consular service, keeps us in close touch with new outbreaks of cholera, bubonic plague, yellow fever, etc. These details, however, give us no perspective, and we remain in ignorance of the general movement of these maladies over extended periods of time.

It is therefore of interest to read what was said before a recent meeting of the Aerztliche Verein of Munich on the last named aspect of epidemiology (*Münchener medizinische Wochenschrift*, March 10) by G. Mayer. The latter gave in brief outline the movement of the great epidemic scourges from 1900 to 1912. Leprosy, prevailing freely in the tropics and subtropics, tends to appear in Italy, France (west coast) and the Riviera. Cholera has moved from India across the Persian Gulf to Mesopotamia, Syria, the Caspian Sea, Persia, the villages of the Volga, Don, Dnieper and Dniester rivers. It progresses in Russian Poland, but has become arrested at the Russo-German and Russo-Austrian boundaries. In 1911 Russia was visited with especial severity from Mesopotamia and Syria, as were also Italy, Turkey, and the Balkan States, and Hungary. The Italian vessels bore cholera to Tripoli and to many other Mediterranean ports.

During the same period the bubonic plague moved from India and China to East Australia, East Africa, South American ports, California. In 1911-12 it extended to North Africa, East Arabia, the Azore Islands, and notably into Brazil.

Typhus, almost confined to Russia and Mexico, has come to light in Spain, while yellow fever prevails in America from Mexico south, along certain routes (West Indies, South American coasts). It has been transported in some degree to North and East Africa. At last accounts it was strongest in Mexico, the West Indies, and Chili.

## Sialoadenitis Sublingualis Acuta Epidemica.

This is the name given to an acute inflammation of the sublingual gland analogous to the inflammation of the parotid gland in mumps. There are instances in which the latter infection involves the submaxillary glands alone, and in extremely rare instances the sublingual glands may be the only ones affected. This rarity imparts considerable interest to the report of an epidemic occurring among the nurses in the Eppendorf Hospital, in which during the month of February, 1912, seven nurses, in addition to one admitted patient, were taken ill with an

infection of the sublingual glands. The cases were observed by C. Hegler, who reports the results of his study in "Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung," Vol. I, No. 2. Of great significance is the fact that at no time during the occurrence of these cases, either in the hospital or in the city of Hamburg, was mumps prevalent, although it is noted that February is the month of greatest incidence of this disease. All of the author's cases began uniformly with the sudden onset of a swelling in the mental and submental regions, which swelling was more or less painful and tender and gave the appearance of a double chin. At the same time a swelling appeared in the mouth over the region of the sublingual glands. In most of the cases there was increased salivation. There was a slight rise in the temperature, and in six instances there were constitutional manifestations such as headache, joint pains, dizziness, and malaise. There were no pathological manifestations in any of the other organs of the body. The blood showed a normal to a slightly increased leucocyte count. The subjective symptoms disappeared within a few days, but the swelling subsided in from four to nineteen days. None of the complications that are occasionally observed after parotitis developed in these cases. The etiology as in the case of the latter disease is unknown. The evidence indicates the existence of a specific microbic factor probably distinct from that giving rise to mumps.

### Galvanization Plus Hypophysis Extract in Induction of Abortion.

With the discovery of the oxytocic action of hypophysis extract was no doubt associated the apprehension that it might prove itself a dangerous abortifacient. This fear soon passed off with the discovery that even at term the new drug is barely able to initiate labor. Nevertheless, it could not be overlooked that this drug is counted upon to exert an abortifacient influence along with other synergistic measures. At a meeting of a Strassburg medical society not long ago (*Deutsche medizinische Wochenschrift*, March 6) Vogelsberger first discusses the history of galvanism as an oxytocic. It was recommended for this purpose as long ago as 1845 by one Schreiber. Forty years later Bayer revived the method, and elaborated a technique which failed in practice only because there was present an unknown quantity, viz., the inability of the current to affect the last stages of labor. The method seemingly lay fallow until the discovery of the oxytocic properties of pituitary extract, which seemed to be exactly what was needed to complete the expulsion of the child. Naturally this combined resource will be employed chiefly only in missed labor and in gestation at term. The possibilities involved in procuring a therapeutic abortion in special cases will doubtless be allowed to slumber until more urgent conditions arise.

## News of the Week.

**Pellagra Work to Continue.**—The Thompson-McFadden Pellagra Commission, which is connected with the Post-Graduate Hospital, New York, has been assured of sufficient funds to continue the work of investigation and will soon open summer field-headquarters at Spartansburg, S. C., where its members worked last spring and summer. The personnel of the commission is the same as last year: Capt. Joseph F. Siler, Medical Corps, U. S. A.; Dr. Philip E. Garrison, Passed Assistant Surgeon, U. S. N.; Dr. Ward J. MacNeal, Assistant Director Department of Laboratories of the New York Post-Graduate Hospital and Medical School; Allan H. Jennings and M. V. King, entomologists of the Bureau of Entomology of the Department of Agriculture.

**City Death Rate.**—During the week ending March 29, there were in New York City 1,660 deaths, giving a death rate of 16.12 per thousand, as compared with a total of 1,617 deaths and a rate of 16.31 for the corresponding week of last year. The death rate for the first thirteen weeks of 1913 was 15.86 as against 15.71 for the same period of 1913.

**New Home for Consumptives.**—The Government of New Brunswick has received a gift from Mrs. James C. Jordan, of an estate of about 800 acres and a residence, to be used as a hospital for tuberculous patients in the incipient stage. The estate is on a high bluff along the Bollet River, twenty miles from Monckton, N. B. The Government has appointed a commission to manage the hospital.

**The von Ruck Serum.**—Medical Inspector E. R. Stitt of the United States Navy, has been ordered to Asheville, N. C., to investigate the work done there by Dr. Karl von Ruck in the treatment of tuberculosis. The Public Health Service has also undertaken to study the remedy and its effects. The results of Dr. von Ruck's studies were reported in a recent number of the Medical Record.

**Prize Essays on Diabetes.**—Announcement is made of the offer of one or more prizes by the Society of Karlsbad Physicians, for essays on "The Treatment of Diabetes Mellitus, with Special Reference to Balneotherapy." The competition is open to physicians of all countries, and essays may be presented in any language. The committee on award includes Professor Dr. Ritter v. Taksch, of Prague; Professor Dr. Luethje, of Kiel; Professor Dr. Ortner, of Vienna; Professor Dr. Schmidt, of Innsbruck; and Dr. Edgar Ganz, President of the Society of Karlsbad Physicians, and they have the option of awarding one prize of 5000 crowns, two prizes of 3500 and 1500 crowns respectively, or three prizes of 2500, 1500, and 1000 crowns. The essays must be in the hands of the judges by December 31, 1913. Further information may be obtained from the Society.

**Civil Service Examinations.**—The New York State Civil Service Commission will hold examinations on May 13, 1913, for the purpose of filling vacancies in the following positions: Assistant medical officer in the Health Officers' Department of the Port of New York, at a salary of $1,500 This position is in the detention and hospital service at the quarantine station, Staten Island, N. Y., and requires a knowledge of cholera, plague, yellow fever, smallpox and epidemic cerebrospinal meningitis. This examination is open only to licensed medical practitioners of the State of New York. Candidates will not be required to appear at any place for written examination, but will be rated on their age, education, experience (particularly with the quarantinable diseases) and personal qualifications as shown by their sworn statements and by answers to such inquiry as the Commission may direct to proper sources of information among persons acquainted with their qualifications.

Physician in the New York State Training School for Girls, Hudson. Examination open to women who are licensed medical practitioners in this State, who have graduated from a registered medical school, and who since graduation have had one year's experience on the resident medical staff of a general hospital, or in a State hospital or institution, or have been engaged for three consecutive years in the practice of medicine. Subjects of examination and relative weights: Written examination, covering anatomy and physiology, hygiene, bacteriology, and pathology; chemistry, organic, inorganic, and physiological; materia medica and therapeutics (drug, psychic, electric, and physiologic); surgery, obstetrics and gynecology; internal medicine and diseases of children; diseases of the mind and nervous system; diseases of nose, throat and skin, 6; education, experience and personal qualifications, 4. A vacancy exists in the position of assistant physician at $1,000 per annum and maintenance, increasing to $1,200, and in the position of physician at $1,500 to $1,800 and maintenance.

Medical Superintendent in the Oneida County Hospital at Rome, at a salary of $2,500 and maintenance for the superintendent and his family. Candidates must be well educated physicians, graduates of legally chartered medical colleges, with an experience of at least six years in the actual practice of medicine, including at least one year's actual experience in a hospital. Subjects of examination and relative weights: Questions relating to hospital management, including the purchase of supplies, 3; questions on general medicine, surgery and hygiene, and the treatment of tuberculosis, 3; education and experience, 4. In connection with the rating of the last subject, candidates may be summoned to Rome for an interview with the examiners. Special credit will be given for actual experience as executive head of a hospital. Open to all citizens of the United States, preference in certification being given to residents of the State of New York.

**A New Kind of Baby Show.**—The Babies Welfare Association of this city is holding a baby show in one of the public school buildings in which prizes are to be given to the healthiest babies and not necessarily the prettiest. It is probable, however, barring some exceptional case of distorted features, that the baby taking the health prize would also have stood at or near the head in a beauty contest, for health and beauty are twins at all ages.

**What Are Twins?**—The commissioners in charge of the dispensing of maternity benefits under the English national insurance act have a hard problem to solve in the case of a Lancashire woman who gave birth to a son on February 24 and to a daughter on April 4. Thirty shillings was awarded to her on the birth of the first child, and the question to be settled is whether the second child is to be considered as cause for granting another thirty shillings, or whether as a twin its birth was covered by the first payment. Under the insurance act the maternity benefit is the same for twins as for one child.

**Gifts to Charities.**—The Harrisburg Hospital of Harrisburg, Pa., receives a bequest of $5,000 by the will of the late William H. Boyer of New York.

By the will of the late Theresa Foy of New York, St. Vincent's Hospital receives a bequest of $3,226.

By the will of the late Lucy Wharton Drexel of Philadelphia the sum of $10,000 is bequeathed each to the Gynecean Hospital and the Hospital of the University of Pennsylvania.

The Society of the Ruptured and Crippled, New York, receives $5,000 by the will of the late Jerome Hilton Waterman.

The Presbyterian Hospital, New York, receives $7,500, and the Adirondack Cottage Sanitarium, Trudeau, St. Mary's Free Hospital for Children, New York, and the Grenfell Labrador Mission $5,000 each, by the will of the late Miss Henrietta Penfold.

**Dr. Herman M. Biggs** of this city is announced as Governor Sulzer's choice for the Commissioner of Health of the State.

**Lee County (O.) Medical Society.**—At the annual meeting at Opelika recently the following officers were elected for the ensuing year: *President,* Dr. W. J. Love; *Vice-President,* Dr. G. H. Moore; *Secretary-Treasurer,* Dr. O. V. Langley.

**In Memory of Dr. L. W. Steinbach.**—A memorial meeting in honor of the late Dr. Lewis Steinbach of Philadelphia was held in that city on the evening of March 30 under the auspices of 42 different organizations. Among the addresses of tribute was one by Dr. Solomon Solis-Cohen on "Physician and Friend."

**Obituary Notes.**—Dr. Frank Warren Chamberlain of New York, a graduate of the College of Physicians and Surgeons, New York, in 1892, and a member of the alumni associations of the New York and Sloane Maternity Hospitals, and of the Washington Heights Medical Society, died at his home on March 29, aged 52 years.

Dr. Joshua W. Beede of Auburn, Maine, a graduate of the Bellevue Hospital Medical College, New York, in 1864, a member of the attending staff of the Central Maine General Hospital, Lewiston, died at his home on March 21, aged 80 years.

Dr. James Clement French of Natchez, Miss., a graduate of the Pulte Medical College, Cincinnati, O., in 1875, a member of the American Medical Association, and the Mississippi State Medical Society, and president of the Adams County Medical Society, died at his home from Bright's disease, on March 19, aged 58 years.

Dr. Leon Straus of St. Louis, Mo., a graduate of the Medical Department of the University of Louisville, Ky., in 1879, and a member of the American Medical Association, the Missouri State and the St. Louis City Medical Societies, and the American Proctologic Society, died at his home from heart disease on March 15, aged 53 years.

Dr. John A. Hayes of Somersworth, N. H., a graduate of the Dartmouth Medical School, Hanover, in 1862, a member of the New Hampshire State and Strafford County Medical Societies, and a veteran of the Civil War, having been retired at its close with the rank of lieutenant-colonel for faithful and meritorious services, died at his home on March 25, aged 75 years.

Dr. Joseph Coddington Young of Newark, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1873, a member of the New Jersey State and Essex County Medical Societies, and for fifteen years chief medical examiner of the Mutual Life Insurance Company of Newark, died at his home on March 26, aged 65 years.

Dr. George McClellan of Philadelphia, a graduate of the Jefferson Medical College of that city in 1870, a member of the American Medical Association, the Pennsylvania State and Philadelphia County Medical Societies, the Philadelphia

Academy of Surgery, the American Association of Anatomists, and the Philadelphia Pathological Society, and professor of Applied Anatomy in the Jefferson Medical College and in the Pennsylvania Academy of the Fine Arts, died at his home on March 29, from an affection of the heart, aged 64 years.

Dr. Nelson Gales Blalock of Walla Walla, Wash., a graduate of the Jefferson Medical College, Philadelphia, in 1861, and a member of the Washington State and Walla Walla County Medical Societies, died at his home, from paralysis, on March 14, aged 77 years.

Dr. Richard Pearce Francis of Montclair, a graduate of Harvard University in 1883, and of the Harvard Medical School in 1888, a member of the American Medical Association, and the New Jersey State and Essex County Medical Societies, president of the medical staff of the Mountainside Hospital, Montclair, and for many years a member of the Montclair Board of Health, died in the Mountainside Hospital, from injuries received in an automobile accident, on March 29, aged 51 years.

Dr. Luther Jacob Saeger died at Allentown, Pa., on March 24, at the age of 36 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1899. He was a member of the Lehigh County Medical Society, of the Medical Society of the State of Pennsylvania and of the American Medical Association.

Dr. Joseph Currie died at Beverly, N. J., on March 24 at the age of 68 years. He was graduated from the Hahnemann Medical College of Philadelphia in the class of 1866.

Dr. William Zoller of Fort Plain, N. Y., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1878, died at his home on April 2, aged 67 years.

Dr. Julian Augustus Mead of Watertown, Mass., a graduate of the Harvard Medical School, Boston, in 1881, a member of the American Medical Association and the Massachusetts State and Middlesex County Medical Societies, a member of the Massachusetts State Board of Health since 1895, and formerly medical examiner of the Seventh Middlesex District, died at his home on March 30, aged 57 years.

Dr. Denis A. O'Brien of Boston, Mass., a graduate of the Harvard Medical School in 1892, died at his home on March 30, aged 45 years.

Dr. Samuel Richmond of the staff of the Atlantic City Hospital, Atlantic City, N. J., and a recent graduate of the University of Virginia, died at the home of his father in Passaic, N. J., on March 31, aged 26 years.

Dr. James A. Egan of Springfield, Ill., a graduate of the Northwestern University Medical School, Chicago, in 1893, a member of the American Medical Association, the Illinois State and Sangamon County Medical Societies, and the American Public Health Association, a lieutenant in the United States Medical Reserve Corps and secretary of the Illinois State Board of Health, died at his home from Bright's disease on March 30, aged 53 years.

Dr. James M. McClure of St. Louis, Mo., a graduate of the Rush Medical College, Chicago, in 1868, and a member of the American Medical Association and the Missouri State and St. Louis City Medical Societies, died at the home of his brother in Princeton, Ind., on March 16, aged 71 years.

# Correspondence.

## THE SELF-LIMITATION OF GONORRHEA.

To the Editor of the Medical Record:

Sir:—The review of my book which appeared in the Medical Record of March 29, gives a wrong impression by only quoting a part of the paragraph in regard to gonorrhea being a self-limited disease. The statement which I made in my book is as follows: "Gonorrhea is a self-limited disease, and the suppuration may be looked upon as an effort on the part of the tissues to remove the invading microorganisms; so that when the last gonococcus is removed suppuration ceases, unless post-gonorrheal lesions in the urethra and infection with other bacteria cause a catarrhal inflammation with secretion, and a discharge of pus continues." Will you do me the favor to print my letter in your next number as I do not wish to be misquoted in your journal.

Henry H. Morton, M.D.

[In the review to which Dr. Morton takes exception, the writer said: "such a debatable statement as 'gonorrhea is a *self-limited* disease' cannot pass unchallenged." In this the author was not misquoted, for the rest of the paragraph simply explains but does not explain away the statement as to the self-limitation of the disease.—Ed.]

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

TROPICAL MEDICINE—DEBATE ON ALIMENTARY TOXEMIA—EFFECTS OF INSURANCE ACT ON HOSPITALS.

London, March 21, 1913.

Tropical medicine has had a good share of attention this week, both the schools having been brought prominently before the public. Prince Louis of Battenberg, president of the Dreadnought Seaman's Hospital Society, took the chair at the annual meeting and pleaded for continued support on the ground that it meets the claims of the sailors of all nations. This year a splendid effort has been made by Mr. Austin Chamberlain to raise an adequate sum to complete the noble monument begun by his father and it is hoped the new buildings will be opened by the King and Queen. The Prince-president urged that in his island kingdom the work of the "hospital dreadnought whose only object was to heal and not to kill" must appeal to all. Mr. Austin Chamberlain followed with an interesting speech advocating tropical research in this school in the capital of the empire.

The Liverpool tropical school comes into a bequest of £80,000 from the late Sir Alfred Jones, a munificent supporter during his life. He left more than £200,000 to be distributed under a scheme which has just been approved by Chancery and which includes this sum of £80,000, which said, Mr. F. C. Dawson the deputy chairman, has come at a most opportune time and would enable them to erect laboratories, wards, and other buildings in immediate contiguity to the Royal Infirmary and within a few yards of the University, the headquarters of the school. The funds for this extension being now assured the work will be put in hand at once. The reputation of the Liverpool school is world wide and its expeditions have been carried on with remarkable zeal. One sent to Jamaica to investigate the vomiting illness so prevalent there is now returning.

"Alimentary toxemia" was the subject fixed upon for full discussion at the R. S. M. and opened on the 10th at a special meeting by Dr. Hale White. There were no less than four papers for the opening day, each of which was enough for a lecture and then there were some speeches before the adjournment. Dr. White's paper was to be a general introduction. He began by objecting to the term chosen for the subject as unscientific for poisoning cases should be grouped according to the variety of the poison, not the point of entrance: "it is a minor matter whether our murderer comes in at the window or the door." The term also, he found too wide as covering an illness caused by absorption from any part of the canal though it would hardly serve for a case of opium poisoning. If it is intended to suggest microorganisms resident in the canal causing illness by passing into the blood we cannot name them nor can we name the poisons made by them if such be intended. If food causes the illness it is somewhat confusing to talk of food poisoning and not toxemia unless the food be infected and on the other hand when not infected to call it alimentary toxemia, as when urticaria follows eating strawberries. The name selected to include the different troubles to be discussed is of secondary importance and Dr. White's objection only a preliminary to a very lucid general statement of the conditions comprised in pyorrhea alveolaris, intestinal stasis, and so on, with practical observations on causes, symptoms, and treatment, as well as some considerate but candid criticisms, especially of the recent extension of surgery in some of these conditions.

The next paper was by Dr. F. W. Andrewes, who took up the bacteriological aspect of the subject. Remarking that the alimentary canal presented ideal conditions for bacterial growth he reviewed its flora and the part played thereby in the production of toxemia. He laid down that (a) in one important group of cases the poisoning is by foreign proteins, these being due to a defect in the liver and generally has little to do with bacteria; (b) the main effect of the bacteria lies in their ability to carry out protein cleavages beyond the capacity of the digestive ferments, with the formation of products which, when in excess, the body is unable to neutralize, and, (c) there is at present little evidence that true toxins, derived from the ordinary flora, soluble or intracellular, play much part in the toxemia.

Dr. Vaughan Harley considered the toxins in question from a chemical point of view. They were probably formed in the canal as were other poisonous products derived from the food as well as from the secretions and excretions, whichever their source they were practically the same. The aromatic substances, indol, skatol, phenol, and cresol, formed by the breaking down of protein by the various bacteria of the canal, appeared to cause symptoms of toxemia.

Dr. Saundby, Professor of Medicine in the Birmingham University, tackled the subject from the medical aspect. He is not so smitten with some of the current notions on food poisons and considers the natural protective agencies, in normal conditions adequate for defence. These agencies are: (1) The digestive secretions; (2) impermeability of the mucous membrane; (3) intestinal mucus which delays absorption; (4) the normal microbes; (5) antitoxic action of the liver. But this protection, he admitted, may be diminished or abolished by inflammation. Alcohol, too, must be regarded with suspicion from its slowing or checking of the digestive processes and inhibiting the protective agencies. Wholesome food in reasonable quantity did not break down the protection and the evidence did not justify the exclusion of animal protein as directly or indirectly a cause of toxemia. When this was actually present treatment was elimination of the poison and reinforcing the protective agencies. Extensive disease of the wall of the colon of long duration and rebellious to other methods might call for surgical intervention.

Mr. Arbuthnot Lane then re-stated his views on intestinal stasis and emphatically asserted the remarkable value of surgical treatment showing from his own practise and that of others throughout the world how defective drainage has been dealt with by operative methods and in numerous cases with brilliant results.

Mr. J. F. Colyer discussed the subject from a dental point of view, two main sources of oral sepsis being caries and periodontal disease, the latter difficult to diagnose at an early stage and requiring each tooth socket to be explored with a fine probe. He held that mouth breathing was a constant cause.

Hospital authorities are greatly perturbed as to the consequences—both present and prospective—of the Insurance Act. They find that subscriptions are falling off or being reduced and at the same time they are called upon to insure their employees. This demand seems utterly unjustifiable considering that these employees had no desire and no need for insurance; they were, in fact, receiving the medical benefits of the Act from the hospitals they served. In the case of the London Hospital the sum thus extracted amounts to £900 a year—a very serious hindrance to the work of this institution, situated in the overcrowded and poor East End and the income of which is only raised with the greatest difficulty. Its zealous and energetic chairman, Mr. Sydney Holland, with officials of the other voluntary hospitals appealed to the Chancellor of the Exchequer to make some amends by relieving them of the duty on legacies. They received for answer that the proposal would involve serious loss of revenue and other demands would follow. And yet, as Mr. Holland remarks, Irish hospitals are exempted. In his thorough way he has gone into the figures of all the hospitals in England and Scotland and finds the concession would cost about £57,250 a year which, he says, is no great amount for the Exchequer and would be a great help to those who have to fight hard for every £5 note. Then he enforces the claim for relief by enumerating the benefits conferred by hospitals and medical schools in all directions and for which no consideration whatever has been shown under the Act or the way in which it has been construed. So "out of pure revenge," as he terms it, he closes his protest by telling those who will leave legacies to hospitals how to divide their bequests so that the charities may receive the largest proportion and the Exchequer the smallest.

A falling off of subscriptions is noticed at some of the voluntary hospitals and is generally attributed to the exactions of the Insurance Act though it is not always possible to trace the cause. An example was quoted at the anniversary of the Italian Hospital on Tuesday when a letter was quoted from a subscriber who for this cause reduced his contribution from £20 to £2 2s. This was urged as a reason why hospitals should be relieved from rates

—a serious impost which costs this charity between £200 and £300 a year. I hear of similar troubles from the provincial hospitals.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

DEATH RATE IN MANILA—PERIOD OF INFECTIVITY IN MEASLES—INSTRUCTION OF THE PUBLIC IN SANITARY MATTERS—HEALTH LEGISLATION IN PERSONALS.

MANILA, P. I., February 15, 1913.

DURING the month of January there was a marked decline in the Manila death rate. For the same month of 1912, there were 698 deaths, whereas, for January, 1913, there were only 502 deaths, which is a reduction of 196. This is by far the lowest mortality record that has been made in Manila since American occupation. There is considerable reason to believe that the many sanitary improvements which have been brought about since American occupation are now beginning to produce results. The new water supply, which furnishes Manila water from an uninhabited water-shed; the sanitary sewers, the prompt isolation of dangerous communicable diseases, clean streets, and effective disposal of garbage and refuse, control of mosquitoes, and the sixty thousand cases per annum that are furnished relief at the Philippine General Hospital, are all, probably, important factors in improving the public health.

The modern views with regard to the period of infectivity of measles, as shown by the work of Anderson and Goldberger, are being given a practical test in dealing with measles cases in Manila. In a girls' dormitory, in which there were quartered 20 girls, none of whom had had a previous attack of measles, there appeared a typical case in a girl who had been outside the dormitory for a number of weeks, and who returned to the dormitory three days after the rash had made its appearance. For a period of 36 hours she came into intimate contact with the remaining girls, but as she was considered to be no longer infective she was simply transferred to an isolation hospital and none of the contacts were quarantined. They were permitted to attend school with several hundred other girls, many of whom had not had the disease. Disinfection of the premises was carried out. More than a month has now elapsed since the case was detected, and no further cases of measles have appeared.

The Bureau of Health has prepared a large number of views illustrating insanitary conditions and their method of correction; the pictures showing the conditions before, and the results after correction. These have been put into the shape of lantern slides and a Filipino physician, who speaks the native dialects, had been detailed to give illustrated lectures on hygiene and sanitation to school children and others throughout the provinces of the Philippines. A number of these lectures have already been given and were well attended, and apparently are useful in educating the public in public health matters. Owing to the few places in the Philippines at which electricity is available, outside of Manila, it is necessary to send a complete electric light plant accompanied by an engineer, in order to operate the lantern. On this account the appearance of the lecturer and his equipment in isolated towns is a rather important event, and directly responsible for awakening much interest.

The annual session of the legislature, which closed February 11th, passed a number of acts which have a direct bearing upon medical matters in the Islands. The opium and cocaine law was amended so that dentists may now administer these drugs under certain restrictions.

An appropriation was made for opening the Southern Islands Hospital, at Cebu. This institution was completed some time ago, but could not be opened until the legislature provided the necessary funds. This hospital marks the beginning of a new epoch in medical relief in the Islands, in that it is the first time in their history that the facilities of a modern hospital are available outside of Manila.

Some slight amendments were made in the provincial sanitary act, so that now only the vote of half the municipalities is required in order to make it obligatory upon a provincial board to vote an equal sum for each dollar appropriated by a town council for health purposes. Formerly a two-thirds vote was required.

An appropriation of $12,500 was made for a diet kitchen in which the pupils of the Philippine School for Nurses may receive instruction in dietetics. The sum of $10,000 was set aside for improving the Sibul Springs baths. The sum of $100,000 was made available for continuing the installation of artesian wells, and $10,000 for continuing the work of the committee heretofore appointed to study the cause of the high infant mortality.

Dr. W. K. Beatty, a medical inspector of the Bureau of Health, has been granted leave of absence to visit the United States.

Dr. Louis Schapiro, who has just returned from leave of absence, has been reassigned as Chief of the Bontoc Hospital Division of the Bureau of Health, with station at Bontoc, in the Mountain Province.

Dr. Collins, of the United States Public Health Service, who is on duty as medical officer on the United States Revenue cutter *Unalga*, en route from Baltimore to Seattle, passed through Manila last week.

1. **X-Ray Examination of the Digestive Tract.**—By F. W. White. (See MEDICAL RECORD, Vol. 82, page 1055.)

2. **Experimental Production of Lesions Resembling Pellagra.**—H. M. Adler has conducted an investigation with the object of determining the reasons for emaciation and anemia in many chronic diseases found among the insane and senile. It has been found that certain patients with emaciation suffer from the effects of a fat intoxication. A similar condition has been shown to exist in certain cases of extreme emaciation due to general paralysis. In these cases it was possible to demonstrate an autohemolysin in the serum after overfeeding with fat in the form of milk or cream. The autohemolysins disappeared regularly when the fats were reduced. These experiments pointed to the existence of a defect in the ability of the individual for handling what under normal conditions was a food. Experiments on the production of pernicious

anemia in rabbits by overfeeding with olive oil, cotton-seed oil, chemically pure triolein, etc., have brought out the facts that an excess of fat may be absorbed by the intestines; that, having been absorbed, it will produce at times the symptoms of acute enteritis, loss of weight and in time a varying degree of anemia, which may be severe enough to closely resemble the pernicious type. In six out of ten rabbits there appeared during the latter part of the experiment, four months or more after oil feeding was commenced, a skin eruption on the inner surface of the ears. This condition was in the nature of a diffuse lesion, characterized by intense congestion and thickening of the entire ear. The ears would become so much thickened that they could be folded over with difficulty, and the congestion caused them at times to appear dark purplish in color. This appearance of the ears was invariably accompanied by acute enteric symptoms such as profuse diarrheas and bloody stools. At the same time the weight of the animal dropped rapidly. The oil feedings were discontinued and the symptoms lessened in severity and disappeared. These experiments seem to the author to be presumptive evidence that a condition which is characterized by a dermatitis and acute enteritis need not be necessarily a clinical entity in the sense of being a specific reaction to a specific causative agent, but that this may be a more or less general reaction common to a large number of pathological conditions.

3. **Abdominal Cesarean Section in Eclampsia.**—J. T. Williams concludes that abdominal cesarean section in eclampsia has a maternal mortality of 48.2 per cent. Vaginal cesarean has a mortality ranging from 3 to 18 per cent., and dilatation of the cervix has a mortality ranging from 7 to 26 per cent. Therefore, abdominal cesarean section in eclampsia should be restricted to those cases in which there is a pelvic contraction sufficient in itself to demand it, and possibly also to early cases of threatened eclampsia at or near term, where the shock of a vaginal delivery seems to offer much greater danger than the added strain imposed upon the excretory organs by cesarean section.

1. **X-Ray Treatment of Epithelioma.**—G. M. Mackee and J. Remer state that the advantages of the massive dose over the fractional dose method in the treatment of cutaneous epithelioma are the following: (1) The accurate measurement of the dose is hardly ever attempted excepting in intensive treatment, so that the method can be said to be accurate and scientific. (2) The patient is spared the necessity of almost unlimited visits to the physician's office. It has been proved that prolonged and excessive exposure to the *x*-rays can produce cancer. It would seem advisable, therefore, in the treatment of epithelioma with the *x*-rays, to give as nearly as possible the exact or minimal amount necessary to cure the individual case. This dose may be divided into several strong treatments, but not into unlimited and oft-repeated mild exposures. The only way to cure a cutaneous epithelioma with the minimum amount of ray is to obtain the desired result in one treatment. If, for instance, six H units of a No. 6 or 7 Benoist ray, administered at one sitting, will cure a given case, the same effect will not be noted if this dose is divided into more than one treatment.

3. **Suprapubic Cystostomy in Carcinoma of the Prostate.**—C. G. Cumston notes that suprapubic cystostomy is the operation of choice in this condition, because it allows one to remove the carcinomatous prostate later on if conditions are suitable. At the present time the occurrence of prostatic cancer is well recognized and it should always be looked for in every case of supposed simple prostatic hypertrophy. In the early stage, before serious symptoms have arisen, a radical operation can be done successfully, but in advanced cases palliative measures alone are indicated. For this reason total prostatectomy should follow suprapubic cystostomy as soon as the conditions admit, the suprapubic operation having been indicated by certain urgent symptoms resulting from the prostatic process. But there is always a notable proportion of inoperable cases, in the author's experience about one out of three, in which the growth has extended beyond its capsule and in which prostatectomy would be useless, if not disastrous. Here one is dealing with what Guyon called the diffused type, and besides not being able to remove the neoplasm completely there is always danger of fatal hemorrhage or a rapid extension taking place immediately after the attempt at removal. These instances are of the *noli me tangere* class, and to them palliative operations alone belong.

5. **Suprarenal Extract.**—J. Aikman summarizes a few important points as follows: Constitutional effects are obtained only by hypodermic injections or intravenous infusions. The hemostatic effect is obtained only by local applications of the drug. Given by the mouth, suprarenal extract has little or no action aside from the local effects. It should not be used in the treatment of pulmonary or cerebral hemorrhages. Failures in the treatment of bronchial asthma are generally due to faulty diagnosis or improper administration of the drug.

6. **Chronic Seminal Vesiculitis.**—A. Hyman and A. S. Sanders as a result of a large number of urethroscopic examinations were led to the conclusion that from the urethroscopic examinations alone it is not possible in the majority of cases to diagnosticate accurately the condition of the seminal vesicles. The appearance of the openings of the prostatic and ejaculatory ducts gives one some idea, however, as to the organ involved. In prostatitis the prostatic ducts generally show evidences of disease, while in vesiculitis the lesions are found in the region of the ejaculatory ducts. As pathognomonic of vesiculitis may be mentioned the oozing of pus from one or both ejaculatory ducts; this latter condition is rarely seen. With the possible exception of this characteristic picture the lesions presented by the colliculus cannot be taken as a criterion of the condition of the adnexa, for similar lesions are often seen in uncomplicated posterior chronic gonorrhea, and even in cases of irritative urethritis due to masturbation or excessive coitus.

2. **Gunshot Wounds of the Abdomen.**—By M. Kahn. (See MEDICAL RECORD, January 25, 1913, page 181.)

3. **The Toxicity of the Salicylates.**—P. J. Hanzlik concludes from his investigations that the mean toxic doses of the different salicylates for adult males and females, respectively, are 180 and 140 grains of the synthetic sodium salicylate; 200 and 135 grains of the natural sodium salicylate; 120 minims of the oil of gaultheria (methyl salicylate); 165 and 120 grains of acetylsalicylic acid, and 100 and 83 grains of salicylosalicylic acid. For females the toxic dose of the salicylates is approximately 80 per cent. of that for males. The toxic dose of salicylosalicylic acid is about 50 per cent.; that of methyl salicylate and acetylsalicylic acid about 60 per cent. of that of sodium salicylate. The toxic dose of the synthetic sodium salicylate for the majority, or about 68 per cent., of individuals of both sexes lies between 100 and 200 grains. Practically the same is true of the methyl salicylate. The therapeutic efficiency of synthetic sodium salicylate is greatest in rheumatic fever and, not infrequently, partial relief and even complete relief are obtained in other conditions. Presumably, there is no relation between the occurrence of albuminuria in febrile and afebrile conditions and toxic doses of the synthetic salicylate. Individuals show idiosyncrasy toward toxic doses of the synthetic salicylate, but no connection is found between these idiosyncrasies and the factors of age, sex, race, and diseased condition. The idiosyncrasy generally varies in the same patient, and is not influenced by previous salicylate medication.

4. **Autoserotherapy in Serofibrinous Pleurisy.**—M. Fishberg believes that this method of treatment is a simple one and ought to be tried in every case of pleural effusion in which the fluid is not purulent. Indeed, inasmuch as in practically every case of pleurisy showing signs of effusion exploratory puncture is to be performed with the view to determining the character of the fluid in the pleural cavity, it is advisable, when the contents of the pleural cavity are found to be serous, that the needle should not be withdrawn completely, but that when its point is brought to the subcutaneous tissue it should be injected then and there. The quantity of fluid to be injected subcutaneously need not be very large; from 2 to 5 c.c. is quite enough. In favorable cases it is observed that within two or three days the subjective symptoms—the pain, the dyspnea, the prostration, etc.—are ameliorated or entirely disappear, while physical exploration of the chest shows that the upper level of the fluid is lower than it was before the injection. Within a week or ten days the fluid in the chest disappears altogether in about 80 per cent. of the cases. In some patients it may be necessary to repeat the treatment several times every two or three days before any salutary effects are evident. In about 10 or 15 per cent. of cases this mode of treatment seems to fail, but even in this instance no harm is done to the patient.

6. **Cancer of the Uterus and Publicity.**—H. J. Boldt states that nothing definite is known as to the cause of cancer. There are no symptoms which, alone, are characteristic of cancer of the uterus. The onset of the disease is so insidious that sometimes the neoplasm has progressed to a stage beyond the hope of cure by any kind of operation, before the appearance of a symptom sufficiently marked to cause the patient to seek advice. The promulgation of knowledge regarding cancer of the uterus through the lay press, as advised at the last meeting of a large national gathering, cannot bring about a lowering of mortality from uterine cancer to such an extent as would be the case if the medical profession—the family physician—did the teaching directly. Information regarding cancer of the uterus in its early stages, through the lay press, is likely to do more harm than good, because there are no characteristic symptoms that apply to that disease alone, and because the principal early symptom, leucorrhea, is one that is present so often in women, in whom there is not the slightest suspicion of uterine cancer that such lay articles are likely to aggravate the nervous symptoms already existing in many, and make neurasthenics of some who are not ill. The family physician must be urged to realize that, in all instances in which there is the slightest suspicion of cancer, his obligation to his patient is to ascertain, by all diagnostic means at his command, that cancer is *not* present, rather than to affirm a cancer diagnosis. When the diagnosis of cancer has been made, an operation for the relief, or the cure—as the case may be—should be undertaken as soon as possible, since, with our present knowledge, surgery offers the best prospect for the patient.

7. **Pneumococcus Meningitis.**—J. M. Brady concludes that the positive diagnosis of pneumococcus meningitis may be impossible during life. A normal cerebrospinal fluid may be obtained throughout the disease. Anatomical changes (encephalitis, meningitis) occur oftener than is usually believed and are the explanation of symptoms from the side of the nervous system which have been regarded in the past as functional (meningismus).

11. **Spasm of the Lumbar Muscles.**—F. M. Pottenger states that the kidney reflex (muscle spasm) is not very difficult to elicit. It is found by placing the patient on a comfortable stool or chair so that his feet are flat on the floor. He is then instructed to sit erect, but relaxed, so that the lumbar muscles are not put on a stretch. These muscles are now examined by light palpation. Any difference in tension should be observed. If one kidney is the seat of an inflammatory process, the muscles on that side will be firmer than normal. If both kidneys are inflamed the lumbar muscles on both sides will be firmer than normal to the touch. It is often plainly visible that the muscles on the affected side are larger and stand out more prominently than the corresponding muscles on the other side. The most important thing to remember in looking for the spasm here, the same as in examining the muscles of the abdomen, chest, or neck, is to have the muscles relaxed. The muscles which are being examined, as well as those with which they are being compared, must be relieved of all tension, otherwise errors will creep in.

16. **Branched Forms of the Tubercle Bacillus.**—S. G. Dixon states that he has shown that the tubercle bacillus has a cycle of life not previously recognized, with a morphology suggesting the higher molds. He is now seeking a culture medium on which, under suitable temperature conditions, the branched forms of tubercle bacilli will reproduce the rod-shaped forms. In the branched forms there is noted a reduced virulence and the author has produced a marked degree of immunity in lower animals with branched forms of the living bacilli.

7. The Nature of Tea Infusions. H. L. Smith.

1. **Intrathoracic Aneurysm.**—F. de Havilland Hall states that the two prime factors in the production of an aneurysm are some degenerative change in the wall of the artery and strain. Syphilitic endarteritis is the most

important causative agent. Thoracic aneurysm is a comparatively rare disease in females. The symptoms met with in intrathoracic aneurysm may be grouped as follows: (1) pain; (2) respiratory symptoms; (3) laryngeal symptoms; (4) circulatory symptoms; (5) dysphagia; (6) paraplegia and hemiplegia; and (7) general symptoms. Pain is one of the earliest and most constant of the symptoms of aneurysm. It may be of three kinds: anginal, that due to pressure, and neuralgic. It is important to bear in mind that angina pectoris of the most typical character may owe its origin to aneurysm, otherwise the physician may be content with recognizing the symptom and fail to discover its cause. Dyspnea is a very common symptom in aneurysm, and may be brought about by various causes. If accompanied by stridor it is highly suggestive of aneurysm. Two kinds of dyspnea are to be recognized—*i.e.* a paroxysmal dyspnea and a gradually increasing difficulty of breathing. The former is probably due to implication of the vagi or recurrent laryngeal nerves, or to compression of the small branches of the pneumogastric forming one of the pulmonary plexuses; and the latter to direct pressure upon the trachea or bronchial tubes. The characteristic cough of aneurysm has been described as ringing, brassy, rough, guttural, or compared to a leopard's growl. The cough may be harsh and dry, or it may be accompanied by a mucous expectoration, sometimes tinged with blood. Paralysis of the left recurrent laryngeal nerve is frequently associated with intrathoracic aneurysm. Among circulatory symptoms may be mentioned pain of an anginal character and throbbing, but it is quite astonishing how little the heart seems to be affected by the presence of an aneurysm unless there be coexisting disease of the aortic valve. In aneurysms affecting the third part of the arch and the descending aorta the patient may experience difficulty in swallowing due to pressure of the sac upon the esophagus. Paraplegia is a rare complication of aortic aneurysm but it may occur as a result of erosion of the vertebræ and direct pressure of the aneurysmal sac upon the spinal cord. The pain and consequent loss of sleep and the general misery caused by an intrathoracic aneurysm usually result in considerable loss of flesh. Emaciation may be more directly brought about by pressure on the esophagus preventing the entry of food into the stomach; or an enlarging aneurysm may compress the thoracic duct causing engorgement of the absorbent vessels and glands, and leading to great interference with nutrition. In some cases the loss in weight is rapid.

2. **Genital Functions of the Ductless Glands.**—W. Blair Bell presents facts which illustrate the influence of the ovaries on the uterus, on the general metabolism, and on the rest of the principal organs of internal secretion. With regard to the influence of the ovary on the uterus it is pointed out that to some extent the implantation of the fertilized ovum is assisted—possibly by the secretion of the corpus luteum. Further, the activity of the uterus is maintained and regular contractions are promoted, probably by the secretion of the interstitial cells. In the general metabolism the total ovarian secretion appears to promote the excretion of calcium and the retention of phosphorus. And lastly, total ovarian insufficiency arouses increased activity in most if not in all the other remaining ductless glands.

3. **Bastedo's Sign in Chronic Appendicitis.**—A. F. Hertz has demonstrated the efficacy of this sign and notes that during the past few months papers have appeared by Rost, Dreyer and Slawinski in Germany likewise confirming its value. The test depends upon the production of pain and tenderness in the right iliac fossa on inflation of the colon with air. For this purpose the author uses an ordinary rubber rectal flatus tube, which is connected by a short piece of glass to a pump, such as that used with the sigmoidoscope. Bastedo recommends that the tube should be inserted 11 or 12 inches into the rectum, but, as the experiments of Goodhart, the author and others have shown that a tube can very rarely be passed beyond the pelvirectal flexure, which is never more than 6 inches from the anus, there is no advantage in introducing it further than just within the ampulla of the rectum—about an inch and a half from the anus. After the tube has been inserted the patient lies flat on his back, and the pump is brought up between his legs. On now slowly pumping air through the tube the colon is seen gradually to distend, and after a certain quantity has been introduced an individual who is not suffering from appendicitis feels a diffuse discomfort in the lower part of the abdomen, but there is no pain unless an excessive quantity of air is introduced, in which case it is not more marked on one side than the other. There is also no tenderness. Patients suffering from appendicitis, however, generally experience pain in the right iliac fossa, even if the pain has hitherto been confined to the epigastrium or the neighborhood of the umbilicus. In one of the author's cases, in which a diseased appendix was subsequently removed, pain was only felt some hours later. Whenever pain is produced, and in some cases in which no pain has been felt, well-marked tenderness is found in the neighborhod of McBurney's point. When tenderness has already been observed in this situation it is always much increased by inflation, but it is also found in cases in which no tenderness has hitherto been noticed in spite of frequent examinations. In a number of instances the author has observed a further exceedingly characteristic symptom; the pain is referred to the epigastrium when pressure is exerted in the right iliac fossa after inflation, the epigastric pain being identical in character with that which formed the chief symptom of which the patient complained.

3. Death by Electric Currents and by Lightning. A. J. Jex-Blake.
4. The Food Requirements of Children. C. Watson.
5. Cases Treated by Radium in the Royal Infirmary, Edinburgh, during 1912. D. Turner.

1. **Glycosuria.**—G. Rankin notes that this condition occurs under a bewildering variety of conditions, and in the present state of knowledge no complete system of classification seems possible. It is met with on recovery from chloroform or ether anesthesia; in poisoning from coal gas; after the administration of thyroid extract and of various drugs; after sudden immersion in cold water; in the later months of pregnancy; as the result of mental shock, etc. It happens as an incident in many diseases of the nervous system; it may be a sequel of the acute infective fevers; and it is met with in organic disturbance of the liver, pancreas, and intestinal tube, and also in disease of the thyroid gland or of the pituitary body. While it is true that carbohydrates ought to be limited in all cases of glycosuria, it is no less certain that in most instances patients do best with a moderate carbohydate element in their diet, and in every case the problem to settle is how far starch, in one form or another, may be given without increasing the urinary sugar. For this purpose the first point to determine is the extent to which the glycosuria depends upon carbohydrate intake. In the matter of dietetic treatment there is one plan which has not received as much attention as it deserves, namely, the effect to be derived from repeated short periods of absolute starvation.

2. **Salicylic Acid and Allied Bodies in Rheumatism.**—R. Stockman finds that the real efficiency of the numerous compounds which have been recommended in rheumatic affections depends solely on the amount of salicylic

acid which they contain or develop in the body. Little is known as to how chemical constitution influences the antirheumatic action of this group of substances. Benzoic acid, formed by the introduction of COOH into benzol, shows this specific action, but when two molecules of COOH are introduced (phthalic acid) the antirheumatic effect is diminished almost to the vanishing point. When, however, OH is introduced into benzoic acid to form salicylic acid, the efficacy is enormously increased, and it looks as if this OH were the determining factor, yet the stereo-isomers of salicylic acid, m-oxybenzoic and p-oxybenzoic acids, have no action. When the OH of salicylic acid is altered into $OCH_3$, as in ortho-methoxy-benzoic acid, all antirhematic effect disappears. That the COOH molecule also has a dominating influence is shown by the fact that in cinnamic and coumaric acids, where it is disturbed, the specific antirheumatic action is completely lost. Methyl salicylate develops salicylic acid in the body and retains the specific action, while the dimethyl-salicylic acid, which does not do so, is inert, and the same holds true in the case of other salicylic compounds, such as salicin (which is active) and populin (which is inactive). The cresotinic acids are the only substances which are known to equal or even approach salicylic acid in efficacy. The prevention of heart lesions, valvular and myocardial, should be the great aim of one's treatment, yet it is notorious that heart lesions occur very commonly even while large doses of salicylates are being administered It is still an open question whether these lesions and rheumatic lesions generally are caused by colonies of microbes or by toxins, nor is it known definitely whether the salicylates act as antimicrobes or as antitoxins. The most immediate explanation of their action is that they kill or injure a causal microbe, but it has also been maintained that the almost instantaneous although transient effect of a small dose given intravaneously points to an antitoxic action, and that when given per os the rapid abatement of symptoms apart from the real cure, as shown by the tendency to relapse, points in the same direction. It is not seriously held at the present day that any of the germicidal remedies can be given in sufficient amount to kill bacteria in the human body. The most one can hope for is that their vital activity and capacity to produce toxins may be abated, and that thereby the natural defensive agencies of the body will be enabled to deal with them more readily and effectively so that the infection is got rid of. Most probably this is what occurs in rheumatic fever under salicylic treatment, and it explains the tendency to relapse if the remedy be prematurely stopped or not given in sufficiently large doses.

3. **Death by Lighting.**—A. J. Jex-Blake states that it would seem as if sudden death by lightning might occur in at any rate three different ways—by failure of the heart, by failure of the respiration, and by failure of both together. In the vast majority of cases the senses are lost at once, and in most death takes place very rapidly if at all. The extreme suddenness with which it must have occurred, as proved by the natural position of the corpse and its placid expression, has often been noted. As is the case in non-fatal strokes, there is reason to suppose that the nervous system is profoundly affected, though no microscopic lesions may be demonstrable. Persons struck and apparently killed by lightning should at once be given plenty of fresh air, their clothes should be loosened, and artificial respiration by Schäfer's or Sylvester's method should be applied and should be continued until either recovery occurs or cooling of the body and *rigor mortis* show conclusively that death has taken place. In the medical writings of from fifty to two hundred years ago one often sees bleeding recommended, and this might well be of service in those cases of lightning stroke in which the heart goes on beating while the respiration stops. If it were immediately—within a few minutes—available to give strong electric shocks to the precordia would be well worth trying in desperate cases. As regards other remedies—such as stimulants in all forms, hot or cold applications, the inhalation of pungent vapors—very many have been recommended, but none seem to have met with any success.

*March* 17, 1913.

**Athletics and Stimulants.**—Professor F. Hueppe shows a most unusual familiarity with athletics in the United States. He begins his article with a summary of the various folk stimulants, and another of the folk athletics. The latter were originally compulsory in character, a part of the daily existence of hunters, mountain dwellers, and the like. The relationship between physical exertion on the one hand and food and stimulants on the other is very intimate; but in compulsory athletics is less marked than in athletics for sport's sake. In the latter the relationship may be one of self-denial, a strict diet without any use of stimulants. When this is pursued not as a fixed discipline, but in the attempt to secure within a limited time a maximum development of efficiency and endurance, the process becomes one of intense hardship and physical torment. During the competition or toward the close of it stimulants are often used and when training is broken there is a very common tendency to go to extremes of eating and drinking. Gotch, the wrestler, has stated that the tortures of training can never be forgotten, while an even more famous athlete ended a season's campaign of sustained effort by a debauch the moment his last engagement had expired. It was of the sort which Americans affect to believe possible only to a German student. The author speaks of the unpleasant impression created by the sight of the boys playing tennis, bicycling and skating with pipes and cigarettes in mouth. Such travesty of sport seems inconceivable, for very much of the benefit of the latter is held to be due to breathing out-of-door air Cocaine has been used more or less on both animals and man as a stimulant in contests. "Doping pills" used in Germany in six-day bicycle races contain both cocaine and caffeine. Cocaine was found upon a test to be very disadvantageous in ski running. The effects of alcohol on physical endeavor have not been brought into harmony, there being evidence on both sides. Much depends on whether the subject tested has some acquired tolerance to the drug. That an abstainer is unfavorably influenced by a prolonged test is conceded. The article will be continued.

**Appendicitis and Scarlet Fever.**—Meyer cites the dicta of several authorities as to the great infrequency of this association. The subject is an interesting one because of the supposed relationship between ordinary angina and inflamed appendix. If the ordinary streptococcus is responsible for the association, we should see it in scarlatina as well as simple streptococcus sore throat. The author has seen one scarlatina case and has obtained notes of another from a colleague. His own occurred in a typical lymphatic child, predisposed to inflammations and hyperplasia of lymphoid tissue. That the case was not a mere coincidence, or a lighting up of a latent appendicitis was crucially shown by the fact that the boy had scarlatina twice, at an interval of about one year and that on each occasion he presented undoubted symptoms of appendicitis. In this connection it is of interest to note that the latter affection has not infrequently developed in the midst of other acute infectious diseases. To return to the author's case the double occurrence of scarlatina was no less a rarity than the appendicitis complication with which it should have become a necessary relationship. He surmises as to whether appendicitis was not the primary lesion, but

concludes finally that the child was the victim of a general infection or sepsis and that the lesions were all metastatic. Cases of this type naturally do not assist in clearing up the border line between scarlatina and ordinary streptococcus sepsis.

*March* 18, 1913.

**Chronic Appendicitis.**—Krecke enumerates the following data which should aid in the diagnosis of chronic appendicitis from other affections such as chronic colitis. The pain in appendicitis as a rule is boring or lancinating, while in colitis there is simply a sense of pressure or discomfort. In the former affection it is naturally restricted to a single area, and further tends to appear in successive crises. Dependence of pain to some extent on outside influences (exercise, menstruation) speaks for colitis, as nothing without either aggravates or mitigates the pain of appendicitis. If a sensitive point like the McBurney symptom is felt at some other region of the abdomen, for example over the sigmoid, it is probably of colonic origin. McBurney's point may be quite insensitive in chronic appendicitis. If a cordlike or cushionlike resistance is encountered over the ileocecal valve it doubtless proceeds from the colon. Altered stools—constipation, fermentation, admixture of mucus—are very suggestive of colitis but do not exclude appendicitis. Improvement under physical and dietetic procedures speaks against appendicitis as due nervous disorders. The author in this comparison is influenced largely by the reproach brought against surgery on account of alleged "revenue" operations performed in which the appendix is found to be normal.

**Biological Diagnosis of Pregnancy.**—Engelhorn has repeated Adberhalden's dialysis tests of the blood of gravidæ and nongravidæ with results which appear to show that the method will be of limited value for the diagnosis of pregnancy. In 60 gravidæ the reaction was positive in 49, which is not a bad showing, but in 48 miscellaneous nongravidæ no less than 31 reacted positively. In this series the individuals suffered in part from various affections of the genitals, of 11 subjects presumably normal 4 gave positive and 7 negative finds, in 12 cases of genital prolapse 10 gave positive reaction; in 8 cases of carcinoma the percentage was the same each way. The author also instituted a series of experiments in which placental tissue was replaced by cancer tissue, fetal, ovary, and liver, etc. The results were paradoxic in the main. Cancer albumin was disintegrated by the serum of gravidæ 10 times in 12; while when the serum of nongravidæ was used the find was almost identical—8 positive in 11 cases. The author is therefore extremely skeptical as to the specificity of Abderhalden's reaction.

**Poisoning by Mould Fungi.**—Dreisbach relates one of those episodes which appear to occur not infrequently in Germany during the harvesting season, and which impose themselves as influenza, typhoid (paratyphus) and similar conditions. The connection of the disease with the threshing of oats was evident to the patients themselves. It was learned that the straw had become mouldy before threshing. The machine used for the latter purpose sent out dust in clouds. Those exposed developed chills followed by fever, great prostration, headache, arthralgia, nausea, anorexia. Upon inspection the face was congested and perspiring, the compression one of apathy from fatigue. There were bronchial symptoms. The tendency of the malady was to run its course within a few days, although certain symptoms, as cough, persisted in certain cases. The public spoke of the affection as the "threshing disease." The author is unable to find any account of a malady due to mould fungi, and thinks the latter could only explain the bronchial irritation. He seems to believe that another factor set up the general infection, despite the fact that zinc vapor when inhaled sets up the picture of a general infection.

*March* 13, 1913.

**Lymphatism and Gastric Ulcer.**—Stoerk sums up an article upon this association as follows: It is in the highest degree probable on the ground of statistics that lymphatism is an essential factor in the genesis of round ulcer of the stomach, especially in the young. The rationale of this association should be somewhat as follows: The stomach of the lymphatic subject should and does contain an increased amount of lymphoid tissue. The projection into the lumen of the stomach of these follicles, by causing the so-called mamellonated state causes a condition of vulnerability. The vessels of the mucosa are also arborescent in this condition and further contribute to the irregularity of the surface. The lymphatic subject also puts up a poor defense to bacterial invasion. While microörganisms do not attack the mucosa primarily they may readily infect ulcers once these are produced and retard their healing. The lymphatic subject is prone to anginas and tonsillitis and acute infectious diseases like typhoid and pneumonia run a course less favorable than in normal subjects. It is also probable that vagotomy is more prone to occur in the lymphatic subject. Another possible causal element is the narrowness of the blood vessels often seen in these subjects. We know that when an ulcer is produced accidentally in the stomach of a normal subject its tendency is to rapid cicatrization.

**Length of Incubation Period of Acute Poliomyelitis.**—Schoug relates a number of cases intended to demonstrate the actual period of latency in the transmission of infantile paralysis. As far as his own material is concerned this should be about four days. There are two possibilities in regard to transmission. First, some blood-sucking parasite may transmit the disease from one person to another direct, which involves the existence of the actual microbic cause in the circulating blood. Second, the germ of the disease may lurk in the nasal discharges of patients and be transmitted to others through the upper air or food passages. The short incubation period announced does not favor one view over the other, although in inoculation by biting flies we should expect necessarily a brief incubation period. In Sweden such a mode of transmission appears to be negatived by the fact that many cases of the disease occur in the winter. Neither is the horse fly so common in that country that many individuals should fall ill at about the same time. Hence the author is obliged to lean toward the theory of propagation by means of the nasal secretion, with participation of healthy carriers.

**Phosphorus in Epilepsy.**—Leubuscher mentions among remedies indicated in epilepsy those which act upon the blood vessels and those which make for disinfection of the alimentary canal. The observation has been made recently that phosphorus exerts power over tetany, an affection commonly believed to depend on autointoxication. He has therefore exhibited phosphorus in a number of cases of epilepsy, giving it over prolonged periods of time. In a number of cases the frequency of the attacks was quite notably lessened. Even after cessation of the treatment the benefit continued and this in the absence of bromide or other therapy. The cases were as a rule severe in type and of long standing. With one exception the epilepsy was genuine in type. The rationale of the treatment is rather difficult of explanation, and Laubuscher is able to say only that we know that phosphorus has the power of modifying metabolism in some manner.

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS,

BY THE INSURANCE EDITOR.

### ELEMENTARY PRINCIPLES OF LIFE INSURANCE.

*Premiums for Limited Payment Policies:*—Reference has only been made so far to the ordinary or whole life policy, a contract payable at death, with equal annual premiums to be paid during the lifetime of the insured. The net annual premium for the ordinary life policy has been determined by dividing the net single premium by a life annuity, the first payment of the annuity being due at once. It may be added here that this computation must necessarily be based on an annuity payable on the first day of the contract year, because the premiums for life insurance policies are always payable in the beginning of the policy year.

A form of policy, probably the most popular, is one in which the payment of all premiums is completed within a stated length of time, say within ten, fifteen or twenty years as elected by the applicant. Such a contract is termed a ten, fifteen or twenty payment life policy. To compute the premium for these limited payment policies, the net single premium for whole life must be apportioned into a limited number of equivalent payments, the divisor being the value of a temporary annuity instead of that of a life annuity.

A temporary annuity is one which, like a life annuity, terminates with the death of the annuitant, but which, unlike the latter, terminates also when a specified number of payments have been made though the annuitant is still living. The value of a temporary annuity is determined in a way similar to that followed in the case of the life annuity. For example, assume that a temporary annuity of $1.00 a year for ten years is granted to the 81,822 members of the hypothetical company at age thirty-five. By calculating the present worth of the amounts required in each and every year during the ten year period, the total fund which must be on hand in the beginning, may be ascertained. Dividing this sum total by 81,822, the number of the original members, will give the value of a temporary annuity of $1.00, at age thirty-five, and terminating with the tenth payment. In a similar way, the value of an annuity for any stated number of years may be determined.

To ascertain the net yearly premium of ten payment life, divide the net single premium of an ordinary or whole life policy by the value of a temporary annuity of $1.00, terminating in ten years. In the same way, the net annual premium for a fifteen or twenty payment life is computed.

*Premium for Term Insurance:*—A term policy is one payable at death provided that death occurs within a period specified in the contract, say, five, ten, fifteen or twenty years. The contract then terminates even if the policyholder still lives. The process of computing the premium already described is again resorted to. It may be assumed, for example, that the 81,822 members of the hypothetical company are all insured for a period of ten years on the term plan at age thirty-five instead of whole life. The company will only have to pay losses for those who die within the ten years. The mortality table shows that 74,173 members will live beyond the period of ten years and will receive nothing in addition to the protection which was extended to them during this time. By consulting the mortality and interest tables the sum of the present worth of amounts required in each and every year to pay the claims during the ten years may be determined, and this amount divided by 81,822, will give the net single premium of a ten year term policy at age thirty-five. Dividing this net single premium by the value of a ten year temporary annuity of $1.00 at age thirty-five, will give the net annual premium required. The holder of a term policy pays purely for protection during the stated term and when he is fortunate enough to live beyond the period in question, he will have received what he paid for at its exact mathematical cost.

*Premium for Endowment Insurance:*—Endowment insurance has been devised for those who wish to make provision for their own futures, in addition to providing for their dependents. To meet this end, the endowment policy is one which is made payable to the insured himself if he lives through a specified number of years, or to his beneficiary in the event of his prior death.

The regular endowment policy is a combination of term insurance and what is known as pure endowment. The latter form of policy is payable only to those who live to complete the endowment period, and according to its terms no payments are due in the cases of those who die prior to the termination of the contract; in other words it is purely investment insurance and the very opposite to term insurance.

To compute the rates paid for pure endowment, it may be assumed there is a proposition to issue a ten year pure endowment policy for $1,000 to each of the 81,822 members of the hypothetical company, at age thirty-five. During the next ten years, 7,649 members will die according to the mortality table. These will receive nothing, but there will be 74,173 survivors who are to receive $1,000 each, requiring a total payment of $74,173,000. The present worth of that sum is $52,582,648.99, and this amount divided by 81,822, gives $642.65 as the net single premium of a ten year pure endowment policy at age thirty-five.

It has been stated that the holders of pure endowment policies receive nothing if they die before the termination of the contracts. If, however, each of the 81,822 members carries term insurance also during the same period, the sum of $1,000 is payable to the beneficiaries of each of the 7,649 members who die during the ten years. By combining, then, the premium of a term policy with that of a pure endowment, the premium of the regular endowment policy is determined, providing for both those who live and those who die.

The chief interest in pure endowment, which is seldom written, lies in the part played by the computation of its premiums in ascertaining the premiums for the regular endowment policy.

---

**Prevention of Fraud in Life Assurance.**—In a meeting of the Life Assurance Medical Officers' Association, on May 1, 1912, in London, Dr. John Howitt brought up the following points of interest. It is of importance to examine the pupils and reflexes generally. Also the urine of patients should be passed in the office and not brought in bottles. In regard to the question on the daily consumption of alcohol it is always more or less a premium on lying and answers to this question must usually be regarded with suspicion.

# Book Reviews.

Outlines of Physiology. By Edward Groves Jones, A.B., M.D., Professor of Surgery in Atlanta School of Medicine, and Allen H. Bunce, A.B., M.D., Associate Professor of Physiology in the Atlanta School of Medicine. Third Edition, Revised. 111 illustrations. Price $1.50. Philadelphia: P. Blakiston's Son & Co., 1912.

This work presents the essential facts of modern physiology as related to the practice of medicine. As an introductory book it can be warmly recommended, but it is too elementary to be used as a textbook by medical students, and does not contain enough even for the average State board examinations. Prospective medical students might read it with much advantage before beginning their medical studies.

The Ship Captain's Medical Guide. Edited by Charles Burland, M.D., F.R.G.S., Senior Medical Inspector of the Board of Trade. Price 2s. London: Published by His Majesty's Stationery Office, 1912.

This handy little volume is meant for use by the captain and officers of those numberless ships which do not carry a physician. The book is issued officially by the Board of Trade of England, and it seems that it should be of the utmost use not only to seafarers but also to others who are far away from skilled medical assistance. The plan of the book is excellent; it is written in plain language, so that there can be no misunderstanding. Under the heading of venereal diseases, the value of prophylaxis is emphasized. The prescriptions at the end of the book are written in full and in plain English, so that they may be copied and taken ashore when possible, without risk of error, or prepared on board ship by any one possessed of normal intelligence.

A Compend of Histology. By Henry Erdmann Radasch, M.Sc., M.D., Assistant Professor of Histology and Embryology in the Jefferson Medical College. Third Edition, Revised and Enlarged, with 111 illustrations. Price $1.25. Philadelphia: P. Blakiston's Son & Co., 1912.

This work has been revised and to some extent rearranged. In its new form it will be found to be a satisfactory guide for the medical student. It is more complete than compends usually are, and yet it is not so large as a textbook. The author has succeeded in providing a small book, which is well arranged, plentifully supplied with the right kind of illustrations, and which bids fair to become as popular as the other volumes of the series.

E. Merck's Annual Report of Recent Advances in Pharmaceutical Chemistry and Therapeutics. Volume XXV. Darmstadt: E. Merck, 1912.

Merck's Annual Report is well known. It collects the most important items from literature and presents them as impartially as possible. The annual edition has now reached the number of 60,000 copies, and it is published in four languages (English, German, French and Russian).

The Science of Hygiene; a Text Book of Laboratory Practice for Public Health Students. By Walter C. C. Pakes, D.P.H. (Camb.), F.I.C., late Demonstrator of Sanitary Science and Bacteriologist to Guy's Hospital, etc., etc. New Edition. Revised by A. T. Nankivell, M.D. (State Medicine), B.S. Lond., D.P.H. (Camb.), etc. Demonstrator of Public Health, King's College, University of London. Price $1.75. New York: D. Van Nostrand Company, 1912.

This little volume should prove a useful supplement to any standard work on hygiene. It gives a very systematic and clear account of the chief processes required in the laboratory, and supplies a concise but adequate explanation of each process. The book deals with analysis of water, milk, butter, flour, bread, coffee, spirits, wines, beer, vinegar, air and soil; disinfectants, microscopy, and meat inspection. There are several helpful illustrations.

Progressive Medicine; a Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D. Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; Assisted by Leighton F. Appleman, M.D. Instructor in Therapeutics, Jefferson Medical College, Philadelphia. December 1, 1912. Price $6.00 per annum. Philadelphia and New York: Lea & Febriger.

The current number of Progressive Medicine contains articles on: Diseases of the Digestive Tract and Allied Organs, by E. H. Goodman; Diseases of the Kidneys, by J. R. Bradford; Genito-Urinary Diseases, by C. W. Bonney; Surgery of the Extremities, Shock, Anesthesia, Infections, Fractures and Dislocations, and Tumors, by J. C. Bloodgood; and Practical Therapeutic Referendum, by H. R. M. Landis. All of these contributions are of value, but special mention should be made of the sections dealing with shock, and anesthesia and blood-pressure. These latter are of more than passing interest.

A Manual of Surgical Treatment. By Sir W. Watson Cheyne, Bart., C.B., Hon. Surgeon-in-Ordinary to H. M. the King; Senior Surgeon to King's College Hospital; and F. F. Burghard, M.S. (London), F.R.C.S, Surgeon to King's College Hospital, and Senior Surgeon to the Children's Hospital, Paddington Green. New Edition entirely revised and largely reprinted with the assistance of T. P. Legg, M.S. (Lond.),F.R.C.S., Surgeon to the Royal Free Hospital; Assistant Surgeon to King's College Hospital; and Arthur Edmunds, M.S. (Lond.), F.R.C.S., Surgeon to the Great Northern Central Hospital, Paddington Green. In five volumes. Vol III. The Treatment of the Surgical Affections of the Joints, the Spine, the Head, and the Face. Price $6.00. Philadelphia and New York: Lea & Febiger, 1912.

The present is the third volume of the new edition of this well known English work on surgical treatment and includes the description of the treatment of the surgical affections of the joints, the spine, the head, and the face.

As it was found impracticable to incorporate the many changes in this field, the book has been entirely rewritten and so altered as to bring it up to date. The authors have intended their book for the practitioner who is believed to be already acquainted with the pathology, symptomatology, and diagnosis of surgical conditions, and have therefore given all their attention to presenting in full the detailed information as to the best methods of treatment. They have succeeded in their task, as is well shown by the favorable reception which the work met with in its first edition.

The present volume is well printed and sufficiently illustrated to meet all ordinary requirements. A more detailed description of its contents is unnecessary in this connection, and it may suffice to say that Cheyne and Watson's Manual constitutes one of the best works of its kind in English text-book literature.

Handbook of Diseases of the Rectum. By Louis J. Hirschman, M.D., Fellow American Proctological Society; Lecturer on Rectal Surgery and Clinical Professor of Proctology, Detroit College of Medicine; Attending Proctologist, Harper Hospital, Providence Hospital, and U. J. C. Clinic, etc., Detroit, U. S. A. With 172 illustrations, mostly original, including four colored plates. Second edition, revised and rewritten. Price $4.00. St. Louis: C. V. Mosby Company, 1913.

The present edition has been entirely rewritten and forty new illustrations, including two colored plates, have been added, and the entire book has been reset. The book is written in the hope that the medical profession will arouse itself to the possibility of this line of work and not allow the charlatan and the advertising quack to take from them work which can be done by the legitimate practitioner of medicine. Special attention has been paid to office work in rectal diseases and the part that local anesthesia plays in this class of work. Dr. George W. Wagner contributes a chapter on "The Feces and Their Clinical Examination," which adds much to the value of the work.

Klinik der Nierensteinerkrankung. Von Dr. med. Wilhelm Karo. Price, 1 Mark. Berlin, Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1913.

This pamphlet, which is No. 6 of the fourth volume of the Sammlung zwangloser Abhandlungen aus dem Gebiete der Verdauung und Stoffwechsels-Krankheiten, contains the etiology, symptomatology, diagnosis, and treatment of nephrolithiasis. The author remarks that the subject of stone in the kidney is of equal interest to the internist and the surgeon. To the latter because the end product of this disease, the stone, is a foreign body which may lead to severe lesions of the kidney substance. The unquestionable relation between trauma and stone formation is also of interest to the surgeon. The investigations of this condition for the past ten years have an important bearing to internal medicine. A positive basis has been given for the intimate connection of calculus and metabolism. Light has also been thrown upon the more exact study of the chemistry and mechanism of the renal urinary secretions which is of direct value for the knowledge of the formation of stones. Further, the chemical examinations of the solubility of the concrements have furnished a scientific basis for a rational internal therapy.

# Society Reports.

## REPORTS FROM THE TUESDAY CONFERENCES OF THE NEUROLOGICAL INSTITUTE OF NEW YORK.

### First Division—Dr. Joseph Collins.

**Fracture-Dislocation of the Cervical Vertebræ Causing Injury of the Fifth Pair of Anterior Spinal Nerve Roots, with Subsequent profound Muscular Atrophy.**—In presenting this case for Dr. Collins, Dr. Sharpe said most operations upon the spinal cord are undertaken to relieve the pressure of old fracture-dislocations of the vertebræ or of tumors. The symptoms and signs of these conditions are becoming more and more clearly defined so that the exact location of lesions of the spinal cord is being made more frequently. Although the localization of lesions of the spinal cord is less difficult than of the brain itself, yet in spinal cord lesions mistakes are not infrequent and the greatest care must be used in each case. The following case is interesting chiefly from the diagnostic point of view. Had the diagnosis of pressure upon the spinal cord itself been made in this case laminectomy would have been advised and it is doubtful if any benefit would have resulted. The difficulties of making a definite diagnosis, however, are many.

This patient, an Austrian Hebrew, 32 years of age, came to the clinic on December 12, 1912. His history was as follows: Six weeks ago, while in good health, he fell from a ladder, which had twisted beneath him, to the roof below, a distance of 20 feet and struck upon the top of his head. He did not lose consciousness but he yelled lustily for help. His friends helped him to his feet and he walked a distance of fifty feet to an ambulance which took him to a hospital in which he remained from 10 a. m. until 7 p. m., when he decided to return home. Even at this time he required some assistance in pulling his undershirt and shirt over his head. During these hours of residence in the hospital he had severe pain in both upper arms, in both shoulders, and in the back of the neck, but he could still raise his head and turn it slightly. He remained in bed for two weeks at home; the pain gradually lessened in severity and the patient regained power to raise the head from the pillow. For the first few days after the accident there was difficulty in breathing and a sensation of weight in the thorax. During the past four weeks the patient has gradually become more and more active—walking about, but the power of both shoulders and the upper arms has not returned, and he is unable to pull his shirt over his head. There is no marked disorder of respiration at present; but he complains of an occasional dull aching sensation in both shoulders and upper arms and at the site of injury, especially when coughing. There is no impairment of sensibility of the arms or legs nor has there been. His voice and articulation seem quite normal.

Patient has had a cough ever since he can remember. Five years ago he was advised to take a "lung cure" in the lower part of Austria. This he did, and the examining doctor there told him his lungs were "all right," but that he had an "enlarged liver" and patient has been slightly "yellow" ever since. The cough has remained the same for years—no definite blood observed; no night sweats. Patient has lost 15 pounds since the accident. Venereal disease is denied. Nocturnal urination—two or three times and it "burns." Appetite, fair since the accident. Bowels regular daily. No digestive complaints. Patient lost the left eye sixteen years ago as the result of a quarrel with his sister, who threw a fork at him, puncturing the left eyeball.

Physical examination shows a man of 32 years whose face has an anxious expression. Somewhat emaciated; yellowish tint to the conjunctiva; coughs repeatedly, raising much whitish phlegm. He stands with his head and neck thrust forward, his square shoulders raised posteriorly and his arms hanging limply down his sides; a mild degree of lordosis. General examination: the patient is wearing a left glass eye; the heart is negative; the lungs are dull at both apices, especially the right, and many moist râles are heard throughout both lungs—a chronic bronchitis. The abdomen is enlarged over the right hypochondriac region, and upon palpation the liver is found to extend downwards to within 3 cm. of the right iliac crest; the left lobe also extends almost down to the level of the umbilicus. Its surface is smooth, and it has a sharp lower border, not tender nor nodular. Spleen not palpable. No free fluid. No masses are to be felt. Laboratory examinations are practically negative.

*Local Examination* shows pupil (right) moderately dilated; reacts normally to light and to accommodation. Cranial nerves, negative. There is marked atrophy of

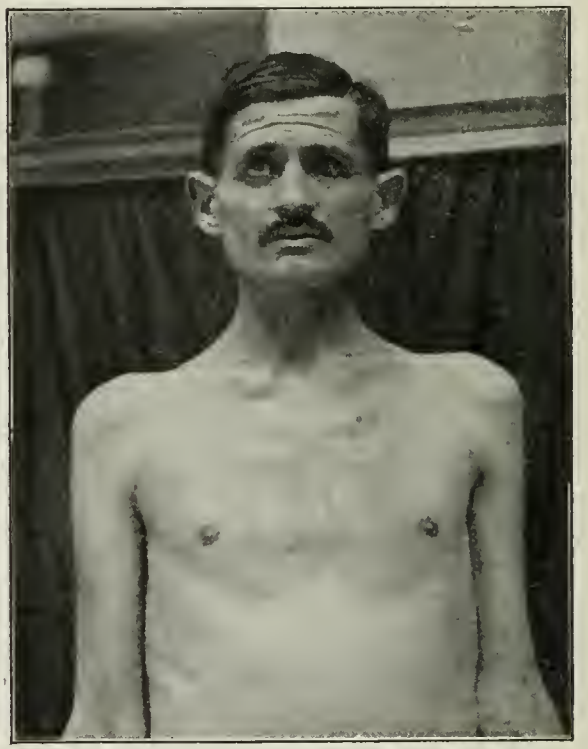

Fig. 1.

the muscles of each shoulder and of each upper arm—deltoids, pectoral muscles, supra- and infraspinati muscles, biceps, triceps, and supinator longi. (See Figs. 1, 2, and 3.) The patient cannot raise the arms up to the level of the shoulders. Use of the forearms and hands normal. No atrophy of the intrinsic muscles of the hands. Grip, normal. No impairment of sensation of touch, temperature, postural, or pain.

The electrical reactions show some variation in the response to stimuli—a general hyperexcitability, with no reaction of degeneration. The deep reflexes of the arms are normal; of the legs, at times those of the left side are greater; at other times, those on the right. No clonus. No Babinski.

At the back of the neck there is a marked prominence of the fifth cervical spine, due chiefly to an anterior displacement of the fourth cervical vertebra (See Fig. 4). Slight tenderness at this point. There is slight limitation of lateral twisting of the neck, also in flexion and in extension.

The positive signs therefore are, marked atrophy of

both spinati, pectorales, deltoids, biceps, triceps, and supinator longi muscles; no reaction of degeneration; the anterior dislocation of the fourth cervical vertebra with a fracture of the fifth cervical vertebra; the arm reflexes are present. It should be noted that there is no impairment of sensation; no alteration of the superficial deep reflexes of the lower extremities; no Babinski; no rectal nor vesical disturbance and no atrophy of the intrinsic muscles of the hand. Theoretically, the lesion which would easily explain this symptom complex would be an injury of the anterior roots of the fifth segment—that is a motor lesion entirely; the absence of sensory disturbances and the presence of the normal reflexes of the trunk and lower extremities would thus be explained. The absence of sensory disturbances in the arms eliminates a lesion of the upper branches of the brachial plexus.

However, when the history is considered that there was no paralysis until two days after the accident, and that then the paralysis came on rather slowly, we are re-

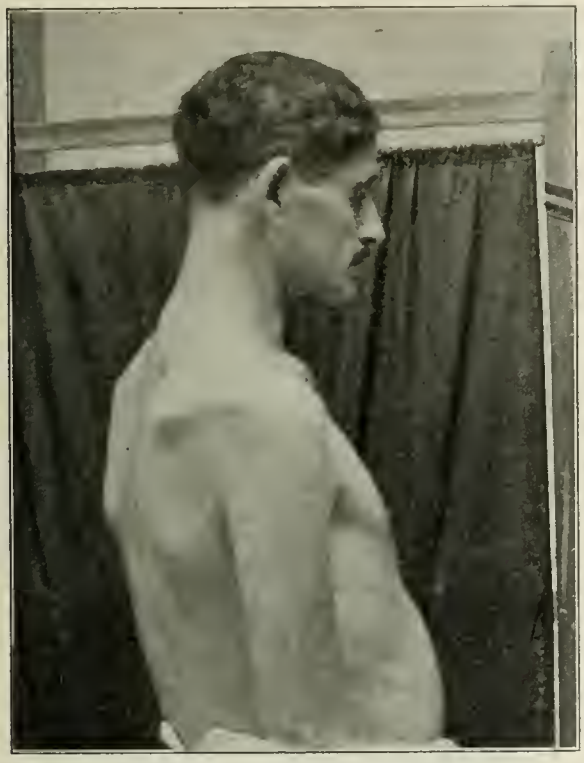

Fig. 2.

minded of the condition of hematomyelia; the fact that there are no sensory disturbances of light touch and of temperature and no change in the reflexes makes this diagnosis rather doubtful; there are cases of hematomyelia reported, it may be said, which have not shown any sensory disturbances. It seems improbable, however, that similar hemorrhages could occur in both anterior horns of the fifth segment—small enough to cause the above signs and yet not large enough to affect the pyramidal tracts anad the sensory paths.

The amount of anterior dislocation of the fourth cervical vertebra is well shown in the skiagraph. It is difficult to conceive of such occurrence without consequent severe injury of the cord itself, but in this case there are no genuine indications of myelomalacia and no signs of real cord injury. On the other hand, the course of the symptoms as well as their occurrence indicate partial destruction of anterior nerve roots, particularly of the fifth segment. Little success has attended efforts to suture torn anterior roots. They are difficult to get at, and when we neurologists and nerological surgeons meet them the proper time for operating has long gone by. What we propose to do now in this case is to make an exploratory incision in the side of the neck similar to that made for repairing the brachial plexus and thus ascertain the condition of the nerve roots as they pass

Fig. 3.

through the intervertebral foramina. If the point of rupture is at the intervertebral foramina it may be quite possible to suture it—that is, bring the distal end of the fifth torn nerve root to the side of the sixth nerve root and so obtain a nerve that will fracture. A man

Fig. 4.

who has pulmonary tuberculosis is not a good surgical risk, but laminectomy is not a serious operation when properly and skillfully done. Without operation his chances of recovery, we think, are slight.

Second Division—Dr. Frederick Peterson.

**A Case of Infantilism, with Pronounced Dysthyroidal Features.**—Dr. R. H. Hoffmann presented the patient, N. F., who was referred by the principal of the DeWitt Clinton High School as a case of mental as well as

physical deficiency. He is twenty-one years of age and has advanced in his studies as far as the average boy of fourteen. He seems to be utterly incapable of mathematics. In the family history consanguinity plays a rôle: his parents are stepbrother and sister; four other chil-

Fig. 5.

dren are normal in mental attainment and in stature. Until his sixth year the patient seemed to be a normal child except that he was somewhat undersized. This dwarfism continued to his twelfth year, during which time his height remained the same. At twelve he entered school and his progress, though dependent upon considerable effort, was practically uninterrupted. He grew very little in the interval and acquired the physical characteristics that stand out so prominently at present, and which place the patient in the obscure class of internal secretion anomalies.

Laboratory investigation has given us practically nothing that would help in isolating a single gland of internal secretion as a causative factor in the production of this infantile state. The blood picture is normal. The urine, feces, and gastric chemism have shown no deviation from natural findings. His sugar tolerance is normal. *X*-ray of the skull by Dr. Cole showed the sella turcica well marked and no abnormal variation. The systolic blood pressure varied between 100 and 110; the diastolic between 70 and 80. One is thus forced to depend rather upon the empiricism of clinical observation and for the time being at least to categorize the patient with those cases that have shown a similar picture and whose study has revealed a definite anomaly of a specific gland or to a greater or less degree of the entire chain of the ductless system. Viola and Prude have found in an exhaustive study of four cases that no single gland was responsible for the infantilism. Bramwell, however, described clinically a pancreatic type, showing an absolute pancreatic deficiency that improved remarkably upon pancreatic therapy. The true myxedematous types of Brissaud are well known and their metabolism has been profoundly studied. The patient is 4 feet, 1½ inches high. (Figs. 5, 6.) He weighs 76¾ pounds stripped; chest, inspiration, 30 inches; expiration, 29 inches; abdomen, 30 inches; thighs, 8 inches above knees, 16½ inches; prominence of calf, 11 inches. As he stands, one is impressed by the rounded, chubby face; the double, folded chin; the fine, thin, silky hair; the absence of the outer half of the eyebrows. The nose is not snubbed. The skin is fine, delicate, and marbled. The extremities are plump and taper at the ends. The body and neck are covered with cushions of fat. There is an absence of hair in the pudendal and axillary regions. The genitals are rudimentary. He has, however, had an occasional erection. The testes are very small, but completely descended. Physical examination shows the heart and lungs to be normal; no anomaly of the abdominal viscera. The teeth are good. The thyroid gland and cartilage are not palpable. There is no presternal dullness. His temperature is normal. His pulse rate has been found to vary between 90 and 110 per minute.

In short, he is not myxedematous and yet he fits most logically into a dysthyroidal picture—in this case, perhaps, a dysthyroidal state that is to a certain degree self-compensating. That this is not the only cause no

Fig. 6.

one will seek to deny. Nevertheless, it stands out preeminently over other symptom groups that we have been wont to class together as belonging to a single gland anomaly.

THIRD DIVISION—DR. PEARCE BAILEY.

**Recovery from Organic Paraplegia.**—Dr. BAILEY presented a patient who had been shown several times before at the conferences when almost completely paralyzed in both legs. Man, aged twenty-six; clerk; admitted September 19, 1910. The patient was an athlete and declared that he was perfectly well until about one month before admission. Then he began to be unsteady on his feet, which was soon followed by numbness in the lower limbs. The limbs ached at times. The symptoms gradually progressed. He left the hospital in October, but returned on December 4 with all of the symptoms aggravated. At this time both lower extremities were spastic, with exaggerated knee- and ankle-jerks, clonus, and Babinski. He now complained of burning sensations in his lower limbs and there was a diminution in all three sensations up to the level of the twelfth dorsal spine. After a short stay in the hospital he again left, only to return January 8, 1911. The burning sensations in the lower limbs were worse and were accompanied by shooting pain in the left groin, the lower limbs were weak and spastic so that he could hardly drag himself around with help. There was some slight sexual disturbance. The right lower extremity was now weaker than the left; both knee-jerks were exaggerated, the right one more so. Ankle-clonus and Babinski were elicited on both sides, more marked on the right. Abdominal reflexes could not be elicited. There was a marked diminution of all three sensations below the tenth dorsal segment.

Although there were no definite surgical indications, experience with other obscure affections in which relief had followed decompression, brought up the question of operation and, at the patient's urgent request, Dr. Elsberg, on January 20, 1911, removed the spinous processes and laminæ of the seventh to tenth dorsal vertebræ. Nothing abnormal was found. One week after the operation, the patient could recognize heat and cold on all parts of both lower limbs, and the hypesthesia and hypalgesia were much less marked. He was able to move his lower limbs much more freely; a great deal of the spasticity had disappeared. Patellar reflexes only slightly exaggerated, no ankle-clonus, no Babinski. Three and a half weeks after the operation there was still some improvement. He could move his lower limbs more freely, but the spasticity was as marked as before the operation, with patellar reflexes again exaggerated; there was bilateral ankle-clonus and Babinski on the right side.

The patient was discharged from the hospital two months later and became steadily worse. He was confined to bed, unable to work at all; lost control of the sphincter; became anesthetic to the waist, *i.e.* developed a typical picture of sensori-motor paraplegia. This condition persisted unchanged for several months. Then improvement set in, gradually, until in the winter of 1911-1912 the man began to walk with crutches and the other symptoms receded. In June of 1912 he called at the hospital, walking stiffly but without support. From then on he progressed rapidly, so that by the middle of the summer he could swim a mile, walk five miles, could jump and run, and had no sensory or sphincter trouble.

To-day, January, 1913, the patient presents few remnants of the paraplegia. He walks easily, can jump, stand on heels or toes, start and stop suddenly. Both knee-jerks are active, but the foot clonus and Babinski have disappeared on the left and are only slightly present on the right, the side which was always most affected. He has no other symptoms, feels in perfect health, commutes every day to business, which he resumed last autumn. No hypothesis satisfactorily explains this miraculous recovery. The patient presented symptoms which pointed unequivocally to organic interference with the spinal cord—namely foot clonus and Babinski, together with other signs of paraplegia. Exploration revealed no pressure or other evidence of disease. The most probable explanation at first, and the one we adopted when the patient left the hospital, was that a patch of intramedullary sclerosis, which was a part of the general disease, multiple sclerosis, was at the bottom of the condition. But the subsequent recovery is more complete than is to be looked for in multiple sclerosis. In that disease there is a wide fluctuation in symptoms which interfere with function, *i.e.* in paralysis, or rigidity, or sensory disturbances. But in the past we have relied on the persistence of the fundamental neurological signs—the foot clonus, the Babinski, the nystagmus, etc.—for diagnosis. If they disappear there is little left to sustain the diagnosis. So in this case. We have watched all the organic signs slowly fade away, until now a one-sided Babinski and slight foot clonus are all that are left.

It seems possible that this case represents one of those little-explored conditions, first described by Horsley, in which changes in intramedullary circulation may bring about the symptoms of definite fecal disease. The successful issue of certain cases of spinal decompression, in which the operation, although it reveals nothing, is followed by recovery, lends some support to such a view.

---

## THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Special Meeting, Held March 7, 1913.*

THE PRESIDENT, DR. BROOKS H. WELLS, IN THE CHAIR.

**The Prevalence of Catarrhal Deafness and Its Economic Consideration.**—Dr. HAROLD HAYS read this paper. (See page 646.)

Dr. W. SOHIER BRYANT said that the individual sustained a tremendous loss in many ways when he was deaf and life insurance companies advanced the premiums paid on the insurance of one who was deaf to 95 per cent. of total disability. He wished to call attention especially to the enormous importance of a knowledge of the prevalence of catarrhal deafness and to its etiology and prevention. Its prevalence in any community was even greater than given by Dr. Hays. With regard to the etiological factors concerned, they all knew that catarrhal conditions of the ear were dependent upon affections of the nose and throat and especially of the latter as well as of the nasopharynx. The nasopharynx was intimately connected, as it were, with civilization, exposed to all kinds of stress as under- and overfeeding, under- and overclothing, and all sorts of causes which resulted in irritation. There were occupational conditions, the business life in the city, and all the conditions incident to the competition for existence. Again there were the impurities in the air, mechanical, gaseous, or bacterial. Dr. Hays had stated that many diseases were derived from the air breathed and one should make it a rule to look at the nasopharynx. The reason for this was that the Eustachian tube opened into the nasopharynx and its function was interfered with when changes occurred in the mucous membrane of this region. Dr. Bryant thought that if they chose to consider their obligations to the public, they could do a great deal by advising people near them how to lead a hygienic life in relation to the nasopharynx and a great deal could be done in spreading this knowledge far and wide. The public was eager to gain information and efforts to this end fell not only upon the otologists but upon the general practitioners.

Dr. PHILIP D. KERRISON said that this was a very interesting subject, but one to which he had given but little thought, *i.e.* the relief of people already deaf. He did not see how these people could be relieved except by some special treatment and what Dr. Bryant had stated about the etiology showed a way by which some good work might be accomplished. The public should be better educated with regard to the prevention of this condition; if the general public understood better the causes of deafness a great deal could be done towards avoiding the lesions which occasioned it; or, after certain lesions were established, leading such lives as would prevent undue progress in their development, as in sclerosis or catarrhal deafness. With regard to so many patients presenting themselves at the clinics, the reason was, he believed, be-

cause so much time was required for examination and patients had to return, and this tended to congest the clinic, a very regrettable thing. As a result less treatment was given for deafness than for aural lesions. If they could have a clinic devoted to the care of those who were deaf it would be most desirable. The only thing that suggested itself to him in this connection was the desirability of the education of the people, so that they could understand the causes of deafness and also what produced the rapid progress of the lesions. There should be some means provided by which deafness and the diseases which gave origin to deafness could be subjected to intelligent and careful study. It was a cause for regret, well recognized by all, that these patients did not get the careful study and treatment in the hospitals and clinics warranted by effects of deafness.

Dr. Charles G. Am Ende said the absolute inability to relieve these conditions described by Dr. Harold Hays vividly portrayed deplorable conditions and imposed upon the general practitioner the importance of the prevention or abortion in the early stages of the diseases leading up to them. From this point of view he wished to report as probably new that chemically pure nitrate of sodium when given in 10 to 15 grain doses dissolved in water, by itself or in admixture, was a very efficient remedy to cut short catarrhal diseases, colds, etc. The crude drug, Chile saltpeter, occasionally dispensed, had very little effect. When the influenza bacillus, caught from a sneezer in a car, or a patient before us, signified its advent about thirty-six hours later by a slight tickling in the region of the middle turbinated bone and irresistible sneezing, but without general systemic symptoms at this time, it was easily killed by brushing up into the nose the following: iodine, one grain; sodium iodide, 5 to 10 grains; distilled water, one ounce and a half. In the case of an old catarrhal subject very satisfactory results were reported from the following: Chlorate of potassium and boric acid, of each, one ounce; alum and chloral, of each, ten grains, dissolved in one quart of boiling hot water, and diluted; three tablespoonfuls of this solution with ten to twelve tablespoonfuls of tepid water for snuffling and gargling as often as desirable. Upon involvement of the Eustachian tube improvement was obtained from the old prescription: iodine, camphor, menthol, each twenty grains, alcohol two drams. Cotton saturated, but not oversaturated to avoid solution running off, with this solution, was loosely packed into a two-ounce bottle with a rubber stopper with two holes, through each one of which a glass tube was inserted. One of these two glass tubes somewhat bent near its lower end reached to near the bottom of the bottle beneath the lumps of cotton, while its other end protruded above far enough for connecion with a compression rubber bulb. The other glass tube reached below just to underneath the stopper, while its other end above connected with the catheter by a rubber tube provided with a conical glass or rubber piece to fit into the catheter.

Dr. William Kelly Simpson believed that the reason people did not apply for treatment of their deafness in greater numbers was because of the universal idea that there was nothing to be done for deafness. Very much depended upon the condition of the nasopharynx and of the nose; in some cases the treatment directed toward the correction of any lesions there would result in the relief of the patient, whereas in another patient with a similar condition in the nasopharynx, or nose, or both, would not be benefited at all. That was an every-day experience. One of the worse phases of medical practice was that they were so often unable to benefit the deaf; they should attempt to make some definite advance in the treatment of deafness, and it should not be forgotten how much depended upon the condition of the nasopharynx and of the nose. Often deafness would continue even after the nasopharynx and the nose were gotten into a normal condition. Gout, rheumatism, and certain toxic conditions were at the bottom of the condition many times; gout especially was one of the most common causes. Dr. Simpson said he would certainly like to see the medical profession get away from the stigma under which it was suffering and see if it could not do something to improve deafness by treatment.

Dr. Harold Hays said that many of these conditions started early in life, and when seen by the specialist there was little that could be done; in other words the alterations of the connective tissue about the ear were such that they might be likened to the condition in the nervous system in cases of locomotor ataxia. To-day it was recognized that there were various kinds of conditions about the ear, such as sinus disease, which interfered with hearing, but if one took a little child and restored the hearing at the time when the pathological process was subacute the child would not be likely to suffer from deafness later on. With regard to publicity it was necessary to instruct people regarding the care of the ears the same as one instructed them how to avoid tuberculosis and infectious diseases. They should be made to understand many of the troubles which resulted in deafness and told how to prevent them. If one totaled up the cases of catarrhal deafness occurring in one's private office and compared them with the cases that appeared at the clinic he would find a larger percentage in the office than in the clinic and this he believed was the fault of the otologist. Very often these patients became sick and disgusted with the time spent on them and just at a time when a great deal could be done for them. It was a noteworthy fact that these catarrhal conditions were not of as much interest to the otologist as were the acute cases. Certain clinics should be maintained for these deaf cases. Unfortunately they were not able to examine the pathological specimens, such as those of the eye and other parts of the body, because one could not take away an ear for purposes of examination before death; after death the pthological changes were such that nothing could as a rule be made out of them.

**The Group of Peritoneal Adhesions Due to Colonic Bacteria.**—Dr. Robert T. Morris read this paper. (See page 645.)

**Photographs in Color of Rare Pathological Specimens Taken from Autopsies at the City Hospital.**—Dr. Orrin S. Wightman described the apparatus used by them in the preparation of the slides. The photographs in color were shown with Lumiere process lantern slides.

Dr. John H. Larkin gave the pathological exposition of those slides.

---

## MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, Held February 17, 1913.*

The President, Dr. Reynold Webb Wilcox, in the Chair.

**Protest Against the Reporting of Venereal Diseases.**—At the annual meeting of the Association, held January 20, the following resolutions, presented by Dr. William S. Gottheil, were adopted:

"*Resolved,* That the recent official request of the New York Board of Health for all physicians to report promptly to them all cases of syphilis, gonorrheal infection, and chancroid, together with the source of infection, if attainable, is an undesirable and useless invasion of the most confidential relationship between physician and patient. The mere compilation of statistics in venereal diseases has no value, and the attempt to make it is a direct incentive to falsification and disobedience to the law. The measure is of value only as a step toward the relegation of the care of this class of cases to the Board of Health, and the ultimate effect will be to promote self-medication and quackery.

*Resolved,* That a committee be appointed to arrange suitable action in regard to this matter, and report at the next meeting of the Association."

This committee, through its chairman, Dr. Robert E. Coughlin, reported as follows: "The special committee recommends that the secretary of the Medical Association of the Greater City of New York be instructed to send copies of the resolutions of condemnation relating to the reporting of venereal diseases to his Honor the Mayor of New York and to the President of the Department of Health." On motion, the report of the committee was unanimously accepted.

**Report of a Case of Hibbs' Operation for Pott's Disease.**—Dr. A. Ernest Gallant presented this report, with photographs and radiographs. The case was referred to him by Dr. J. D. Trezise of Brooklyn. The patient, a female, thirty-four years old and weighing 101 pounds, stated that she had had deformity of the spine for the past two years, and an *x*-ray picture taken October 2, 1912, showed the tenth, eleventh, and twelfth dorsal vertebræ to be affected. The operation was performed on October 5, and by the end of four weeks the patient was entirely relieved of pain. She was kept in bed for a few weeks, and afterwards wore a brace. Later, she was fitted with a suitable corset and returned to her home in Pennsylvania. Early in December she wrote that she had walked two miles and on December 30 that she had gained six pounds. Dr. Gallant stated that the *x*-ray pictures did

not show whether there was actual ossification at the seat of operation at present.

**Eyestrain: Etiology; Indirect Effect Upon the Function of Other Organs; Symptomatology.**—Dr. Isaac Hartshorne said that the term eyestrain was generally understood to mean that varied and complex group of symptoms resulting from errors of refraction or imbalance of ocular muscles. Having explained the conditions in myopia, hyperopia, and astigmatism, he said that in high errors of refraction the ciliary muscle soon tired of trying to overcome the defect, and the blurred images of irregular diffusion remained to irritate the retina. Low hyperopic errors were easily overcome by ciliary action, and as in such cases the constant stimulation to see better resulted in either muscular fatigue or hypertrophy, or both, low errors were often more productive of malfunction than high ones. Since the myope could not impove vision by ciliary effort, he received on the retina the full effect of the irregular diffusion produced by whatever amount of astigmatism he might have. The indirect effect of eyestrain upon the function of other organs could be appreciated by a consideration of the nerve elements involved in the ocular mechanism. For a muscle to do enough work to become hypertrophied or fatigued required an abnormal amount of motor nerve supply. Individuals with a superabundance of nerve force did not feel any effects from this kind of energy expenditure, while in those possessed of only a limited amount an extravagance on the part of one organ meant a lack of normal supply to and consequent malfunction of some other organ. The fact that one-fourth of all the cranial nerves were required to supply the eye-muscles showed how much motor nerve energy was needed for normal ocular function, and also how great the opportunity was for a waste of nerve force when these muscles were overworked. Retinal irritation from irregular diffusion and congestion of the muscles were transmitted as sensations of pain by the trifacial nerve and caused much headache. Muscular fatigue resulted in variations in the distinctness of vision, and the effort to innervate the tired ocular muscles was often productive of twitching of the eyelids and of the facial muscles, as seen in the various habit spasms. Some of the local symptoms of eyestrain which had been noted were screwing of the lids in myopia and astigmatism, elevation or depression of an eyebrow, abnormal wrinkles, constant blinking of the lids, tilting of the head, many chronic inflammatory conditions of the lids and conjunctiva, and enlarged pupils and photophobia. While some patients showed local inflammatory conditions and apparently no reflex irritation, others would appear to have no ocular deformity, but presented reflex disturbances which, after other organs had been excluded, might be regarded as due to ocular difficulty. The speaker's experience agreed with the quoted statement that an ocular cause might be suspected in all headaches which occurred regularly and got worse in the afternoon, which were increased by close work and relieved by rest and on holidays, or which occurred only during certain occupations. Many of the symptoms of fatigue, irritability, and nervous irritability from which women suffered during the menopause were often really due to the sudden onset of presbyopia. Functional disease of the digestive tract associated with continued application and nervous tension and cases of dizziness and so-called bilious attacks, were often due to eyestrain, as evidenced by the relief afforded by glasses. Again, some cases of migraine, epilepsy, chorea, neurasthenia, and psychasthenia were benefited by removing whatever irritation might be present from eyestrain. Glasses were a labor-saving device to prevent or offset the disastrous results of eyestrain. Refraction was an art, and not an exact science. To obtain the best functional results the hyperopic, myopic, or astigmatic errors should be estimated as closely as possible. Astigmatism, the most difficult part of refraction, required special attention, involving training, care, patience, and consequent skill. Lens grinding was an exact science, and the time would come when the profession would be as zealous for accuracy in optical production as we were now becoming for purity in drugs. At present it was a fact that about fifty per cent. of oculists' prescriptions were not accurately filled.

**Clinical Indications for the Mastoid Operation.**—Dr. W. Sohier Bryant read a paper on this subject. Formerly, he said, the accepted indications for mastoid operation were: symptoms of cranial and hemic complications, labyrinthine suppuration, fistula of the mastoid process, facial nerve or abducens nerve paralysis, fluctuation, edema, or deep tenderness over the mastoid region, rise of temperature, and headache—all associated with middle ear suppuration and chronicity. At times there was difficulty in estimating the true importance of the various symptoms, and it often happened that cases which required immediate operation were delayed because of absence of some of the classical symptoms. Atypical cases with absence of any direct evidence of mastoiditis were either not diagnosed until it was too late to save the patient's life, or a tedious recovery followed a delayed operation. Until comparatively recently mastoid operations were on principle deferred until softening of the bone had occurred; expectant treatment holding out the hope of convalescence without operation. Formerly also the prognosis of the results of the operation were most discouraging: usually a slow, weary convalescence with many painful postoperative dressings, and, what was worse, considerable impairment or even complete loss of hearing. It was no wonder, therefore, that the operation was delayed as long as possible. The history of the recent development in the diagnosis, prognosis, and treatment in mastoid surgery was marked by four brilliant achievements: the deductions from bacterial examination of the discharges, the use of the Röntgen ray in disclosing intraosseous conditions, the short convalescence, and the improved hearing after the operation. The present-day indications for a mastoid operation, therefore, included, in addition to the former ones, several definite elements of preeminent value in both diagnosis and prognosis. The most important of these indications were: (1) rise of temperature unaccounted for and the toxic appearance of a patient suffering from inflammation of the middle ear or with a history of such inflammation; (2) the infallible indication of the presence of the *Streptococcus mucosus* in the discharge, together with the determination of the condition of the mastoid, reinforced by the skiagram; (3) the demonstration of a solid mastoid in the presence of middle-ear suppuration. The histological examination and count of the blood, though of little significance alone, was useful as a diagnostic and prognostic point. In the presence of *Streptococcus mucosus*, or with the unaccountable rise of temperature and the toxic appearance of the patient suffering from middle-ear inflammation, operation was infallibly indicated in cases where the skiagram showed a diseased or doubtful appearance. An observation of the greatest importance was that a mastoid infection due to *Streptococcus mucosus* runs a remarkably insidious course, with absence of objective symptoms and slight tendency to resolution. Involvement of the mastoid by this microorganism demanded an immediate operation, for if it were delayed it would be found that soon an emergency operation would be demanded. Like the bacterial differentiation, the skiagram was of especial value in cases which, without its use, might be overlooked. It had been observed that in normal temporal bones the interior structure of the mastoid varied considerably, grading from pneumatic cellular, through diploetic, to dense ivory, bone. Clinical observation showed that in pneumatic mastoids infection tended either to frank abscess formation or resolution, while in cases where diploetic or dense bone surrounded the mastoid antrum it tended rather to eventuation in chronic middle-ear suppuration or to the development of serious intracranial or hemic complications. The skiagram also gave a differential diagnosis between middle-ear suppuration complicated by otitis externa without mastoiditis and otitis externa with mastoiditis, and where both ears were affected it was useful in determining which ear demanded operation, or whether both ears should be operated upon. The means by which the time for operation was determined were the following: (1) The history of the case; (2) the condition of the ear as determined by inspection; (3) the presence of general sepsis; (4) symptoms indicating intracranial complications; (5) the formation of an abscess requiring surgical drainage; (6) a skiagram of the mastoid region; (7) the bacterial examination; (8) chronic middle-ear suppuration not yielding to other treatment or with cholesteatomata; (9) acute suppuration of the middle ear unreasonably prolonged; (10) acute suppuration with the skiagram showing absence of the antral pneumatic cell system; (11) suppurating labyrinthitis. Recourse to the Röntgen ray cleared up a doubtful diagnosis, giving, in connection with the clinical symptoms, positive indications for or against operation. In the pneumatic mastoid suppuration it was advisable to delay operation until the formation of abscess, while in the dense mastoid, suppurative mastoid inflammation was sufficient indication for operating at once. The prognosis following the mastoid operation, if the operation were delayed, was much the same as formerly, but cases operated on at the earliest crucial moment indicated gave a prognosis of speedy convalescence, absence of complications,

and restoration of normal hearing. In conclusion, Dr. Bryant said he would say: (1) operate when mastoid abscess is present; (2) operate on mastoiditis due to *Streptococcus mucosus;* (3) operate in the presence of intracranial or hemic complications of middle-ear infection; (4) operate on mastoiditis, acute or chronic, when the bone is of the solid variety. The former indications for operation were, as we knew, very vague. Now, with our more definite and specialized indications, there was no reason to delay an operation which had in the end to be performed. It was impossible to lay too much stress on the point that we should determine as early as possible whether operative interference was demanded.

**The Combined Laboratory and X-Ray Indications for the Mastoid Operation.**—Dr. George Sloan Dixon, in this paper, said that during the past eleven years 5,496 examinations of aural pus had been made at the Eno Laboratory of the New York Eye and Ear Infirmary. Of these, 26.6 per cent. were mixed infections, where, with a large number of germs present, it was not advisable to charge the infection to any particular germ. The majority were chronic cases, and where a radical mastoid operation was done the mastoid smear usually showed mixed germs. Streptococcus occurred as the predominating germ in 24.8 per cent.; *Staphylococcus* (*aureus* and *albus*), 7.4 per cent.; *Streptococcus mucosus capsulatus*, 4.8 per cent.; spirillum of Vincent, 1.8 per cent. The remaining 22.4 per cent. was made up of miscellaneous and negative microorganisms, among which were the tubercle and Friedländer bacilli. As the mastoid pus in cases coming to operation, as well as the pus from the aural cavity, was examined, comparison showed that the predominating germ in the canal was found in the mastoid pus with sufficient frequency to justify the regarding of the predominating germ in the discharge from the middle ear as responsible for the mastoid involvement. In the matter of the relative virulence of the various microorganisms in acute suppurative processes about the middle ear Dr. Dixon's experience had led him to regard the *Streptococcus mucosus capsulatus* as standing first, *Streptococus pyogenes* next, pneumococcus third, and staphylococcus fourth. He desired to reiterate, with special emphasis, a statement he had made a number of times, namely, that among the microorganisms found in the middle ear the *Streptococcus mucosus capsulatus* in a manner stood alone; being the most insidious and destructive the otologist had to combat. A case in which this was the infective germ would, indeed, tend to recovery equally with other forms of serious infection, provided it was seen early and proper drainage was established; but the great danger from it was to be found in neglected cases or those in which all the acute symptoms had subsided, though the otorrhea persisted and the *Streptococcus mucosus* was present. Cases of this character demanded at least an exploratory mastoid operation. As a rule, every day over two weeks' duration was an additional and increasing menace to the life of the patient. To illustrate the force of this statement he gave brief histories of six cases ending fatally which had been picked at random. While other forms of infection might be equally dangerous, in them there was little likelihood of such a complete cessation of symptoms, and the danger signals were pretty constant. In cholesteatoma the finding of cholesterin crystals in specimens from the canal or attic might aid in the diagnosis. The microorganisms found in this condition were not likely to be of much importance. In mastoiditis the blood count might be an excellent indication of the resistance of the patient or the onset of complications, but gave little information as to the condition of the mastoid itself. In blood cultivations we had an excellent means of determining whether the patient was suffering from bacteriemia or not, and a positive cultivation in the presence of middle-ear suppuration might be regarded as evidence of thrombosis of the lateral sinus, provided that all complications of a suppurative nature below the neck could be eliminated. If any advantage was to be derived from mastoid radiography, some knowledge of the variations met with in the normal mastoid process was, of course, necessary. Having made some reference to these, he said it might very properly be asked what we might reasonably expect to be obtained in the way of information from an *x*-ray examination of the mastoid. First, it would show, in the vast majority of instances, the location of the lateral sinus, judged by the shadow of the anterior margin of the groove in its relation to the meatus and its angle to Reid's base line—which was most important. (Illustrative cases cited.) Second, we could learn the type of bone, the location of the large cells, whether the sinus was covered with cells or not, and the extent to which they had developed into the zygomatic region. If cells did not show on the diseased side, and did show on the normal side, the chances were about three to one that the pathological bone was of the same type. If no detail were found in the plate of the affected side the chances were about five to one that the mastoid was diseased; though the clinical symptoms must back up the plate. (Cases cited.) Third, it was possible to diagnose perisinous abscess occasionally. More experience and improved technique should increase the number discovered. Epidural abscess, if it were not in line with the sinus, should be diagnosed at least in a small proportion of instances. (Cases cited.) Fourth, fractures of the mastoid process could be shown, but not invariably. Stereograms would aid in these cases. Fifth, faults in the canal wall and tegmen tympani and antri might be shown. Furunculosis of the canal frequently gave marked symptoms, and in the vast majority of cases the diagnosis could be cleared up by an *x*-ray examination. (Cases cited.) It could not be gainsaid that *x*-ray examination of the mastoid was of great value. Ordinary common sense must be used in reading the plates, and the findings should be supported by the clinical symptoms. Where the latter alone were not sufficient for a diagnosis of mastoiditis a positive plate would often supply conclusive evidence for immediate operation. Anything which would add to our knowledge would increase the chances of the patient's speedy recovery. The clinical symptoms were all-important; without them our modern aids were of little value. We might have a rather violent streptococcus infection in the canal, or a pneumococcus infection which looked vicious in the smear, recover after myringotomy, even though there might have been considerable mastoid tenderness; and a *Streptococcus mucosus otitis* media might eventuate in the same way. Not infrequently, however, the clinical symptoms in this form of infection were not sufficient to warrant surgical intervention. When the acute stage had passed away we might have none, and the blood count might be normal. Only the otorrhea remained, and possibly even this might have ceased. If in these cases further clinical symptoms were waited for, the chances were greatly in favor of their indicating meningitis or sinus thrombosis when they did arrive, instead of a simple acute mastoiditis. A positive *x*-ray plate in such a case, taken in connection with the form of infection, settled the diagnosis and made the mastoid operation, with as little delay as possible, imperative. Staphylococcus infections seemed to allow more latitude than any of the others, but even these would give plenty of trouble if the drainage was poor. A certain number of cases were met with in which symptoms of sinus thrombosis were the first indication that the time for operative interference had arrived. Here a positive blood culture would, of course, settle the diagnosis, provided that other sources of infection of the blood stream could be eliminated. In these cases the differential blood count was variable, and could not be regarded as affording any very positive assistance; but a large leucocyte count and a high polynuclear percentage were suspicious.

Dr. Gorham Bacon said that for a good many years he had worked with much satisfaction with Dr. Dixon in this class of cases. It was of very great value to know the nature of the infection, not only in one ear, but in both. In certain instances there was a mixed infection on one side and a very virulent infection on the other. The fact of such virulent infection indicated that the real trouble with which we had to deal was probably on the side where this was found. Hence, the laboratory findings helped very much in this class of cases. On the other hand, we might have sinus thrombus with negative blood cultures, and with a positive blood culture fail to find a thrombus in the sinus; and we had, therefore, to rely more on the clinical indications than those furnished by the laboratory. The clinical were the most important, though the others undoubtedly helped out. He could endorse all that Dr. Dixon had said in reference to the pathological importance of the *Streptococcus mucosus capsulatus*, and when in any case, he learned from the latter that this microorganism was present he always operated earlier than he might otherwise have done. The laboratory and *x*-rays were of very great assistance, and he was convinced that in the future these aids would become of even more value than at present.

Dr. Edward B. Dench said that as to the effects upon the hearing, if the operation were done early this was seldom impaired, and his experience was that patients heard as well after the operation as before. This was an argument for operating early, and it should be borne in mind that the simple mastoid operation, if done sufficiently early, was not a dangerous procedure. As to infection by the *Streptococcus mucosus capsulatus*, during one winter he had thirteen cases of this, most of them in private practice, and out of these only two came to a mastoid operation. Still, notwithstanding this experience, he agreed

that this microorganism was the most dangerous we had to deal with. He would say, however, that a case of such infection was not dangerous provided that it was drained early. But the patient should be watched very carefully for a long time, for one never could tell when serious trouble might suddenly develop, even though the patient was apparently in perfect health. He believed that the surgeon should recognize the presence of danger in every case of this form of infection, though it was not necessary to open the mastoid immediately in all instances. Dr. Dench had noticed that Dr. Bryant placed the skiagraph number 5 in his diagnostic table. He himself would certainly give this a much higher position on the list, as he considered it of very great importance in the diagnosis.

Dr. T. Passmore Berens said that of the fourteen cases of mastoiditis radiographed by Dr. Law of the Manhattan Eye, Ear, and Throat Hospital during the past two weeks, as they presented themselves at his (Dr. Berens') clinic, his reading of the plates in every instance was confirmed on operation. Dr. Dixon's *x*-ray and other work was convincing, and could not be too highly praised, and he wished to congratulate Dr. Bryant on his able handling of his subject. He agreed with the latter as to the indications for operation, but thought he had not sufficiently emphasized the fact that there was a class of cases with practically no subjective symptoms which had been called "latent mastoiditis." Latent mastoiditis had, in many instances, simply a discharge from the middle ear, and this was frequently the only symptom on which we had to work—often there was no pain on pressure, no edema, no demonstrable sagging of the walls of the external canal; the blood-count might be normal, fever was absent, and the patient might claim complete freedom from other discomfort—and yet the mastoid might be necrotic and full of pus. There was still another class of cases in which the drum-membrane might be intact, with but little if any redness in it, and there might be simply vague pains referred to the ear and to that side of the head. Even here the blood count might be normal and fever lacking, and yet the mastoid might be full of pus, while operation might uncover a perisinous abscess. Dr. Bryant had not emphasized at all too strongly the importance of early operation in cases of *Streptococcus mucosus*, but it was well to remember that even the comparatively innocent staphylococcus might invade the meninges and cause death. He had seen many cases such as he had mentioned, and it was just these atypical cases which tested our diagnostic skill to the utmost. The most promising aid we possessed was the radiograph, made and read by a skilled and experienced radiographer. The importance of the facts impelled him to emphasize by repetition and to take the liberty of adding to Dr. Bryant's first two conclusions, so as to make them read: Operate when mastoid abscess is present, no matter what the infection may be and even in the absence of fever; operate very early in the presence of *Streptococcus mucosus*, even when the symptoms of a mastoid abscess are comparatively slight.

Dr. Charles E. Perkins said he thought that as time went on we would rely more and more upon the *x*-ray examination to aid us in the diagnosis of doubtful cases. Some two years ago he had reported four cases of mastoiditis without apparent involvement of the middle ear. One of these patients had had a swelling behind the ear for about three months. The fundus of the canal and membrana tympani were normal. At operation a large perisinous abscess was found. The infection in this instance was the *Streptococcus mucosus capsulatus*. In another case, which he had seen just before death, the fundus was normal, but at the autopsy mastoiditis, sinus thrombosis, and meningitis were found. In this case an *x*-ray examination early in the course of the disease would doubtless have cleared up the diagnosis and perhaps saved the patient.

Dr. James F. McKernon said that the importance of the evidence afforded by bacteriological investigation in this class of cases was now generally recognized. Yet when he had asserted this in 1896 it was received with laughter by the surgeons of the New York Eye and Ear Infirmary. He had waited to hear Dr. Bryant say something about the atypical cases. The typical cases were easy of recognition, but those on the borderline were more difficult. There might be no tenderness over the mastoid, but there were two significant signs. The first was a marked diminution in audition on the affected side, and the second was that when a speculum was inserted there was found a general narrowing of the lumen of the canal, though most marked as regards the superior wall. In addition, the appearance of the tongue would indicate the presence of an infection. Again, in children the development of serious trouble was sometimes very late. There might be nothing to attract attention but a continuous discharge, but the quantity of this would show that it came from a reservoir of greater capacity than the middle ear. While the blood examination and *x*-ray were undoubtedly of great confirmatory value, he would refuse to operate in any case in which he had to depend upon the evidence afforded by these alone.

Dr. Joseph A. Kenefick said that he, too, would emphasize the atypical cases as of the greatest importance to the general practitioner. Headache was a sign which ought not to be disregarded, and especially headache at night. Tension was a necessary result of mastoiditis, and this, naturally, was relieved to some extent when the patient was in the upright position, but continuous when he was in the recumbent posture. In mastoid disease the sooner one operated, the better. In the matter of diagnosis, in relation to the type of infection present, he depended upon the findings by Dr. Dixon. Mastoiditis often could be nipped in the bud in infection of any type, and in every instance it was essential that the drum membrane should early be slit from top to bottom.

Dr. Arthur B. Duel said that all seemed now to agree as to the value of smears. This was not formerly the case, as it was claimed by many that only cultures could be of importance. For many years it had been his invariable practice to make smears from the ear, and he had come to look upon the findings as of prognostic value. Dr. Dixon's work had been of great value. As to infection by the *Streptococcus mucosus capsulatus*, we should not be deceived into inaction by the fact that no very serious symptoms developed, provided that the discharge continued. These cases ought to be operated on precisely because the *capsulatus* was there, when the discharge continued for more than a fortnight owing to the fact that tremendous destruction often occurred with no warning symptoms until intracranial structures were involved. The pneumococcus would produce high temperature, as it did in pneumonia, and this was likely to subside by crisis, without giving rise to mastoiditis. He believed the *x*-ray would prove to be of incalculable value in diagnosis as experience increased.

Dr. Dixon, in closing, said that we might have sinus thrombosis, and yet negative blood cultures. This had been shown in two cases in the service of Dr. Robert Lewis, where the internal jugular vein was completely blocked.

Dr. Bryant, in closing, said that the skiagram afforded the final recourse in the diagnosis and prognosis of mastoiditis, that no case should be operated on without it, and that all cases of obvious or suspected middle ear suppuration should be radiographed.

**The Results of Tonsillectomy.**—Dr. Bryan DeForest Sheedy read this paper. (See page 654.)

Dr. Frank C. Raynor said that for a great many years he had done tonsillectomy practically exclusively. He had had some of the deformities mentioned in the paper, but almost always an essentially normal throat afterward. When the tonsil ran very high up there was a greater risk of some deformity. He had met with no marked impairment of function, though it was difficult to follow up hospital cases. Most of his operations had been in children, and in this class of patients, on account of the gagging and other trouble caused, local anesthesia was not practicable. In practically all his cases he had employed general anesthesia, and this he thought preferable on account of the comfort of both operator and patient. He had been much interested in Dr. Sheedy's description of his method, and would certainly give it a trial.

Dr. William K. Simpson said that the question of tonsillotomy versus tonsillectomy was an old and vexed one. There was no doubt in his mind, however, that a good tonsillotomy was better than a bad tonsillectomy. In skilful hands the old operation, in many instances, could be done as effectively as so-called tonsillectomy. It was certainly a matter of wonder why tonsillectomy had not always been the one operation, and the most probable explanation was that something must have happened to throw discredit upon the procedure. We now had a great variety of methods for removing the tonsils, and it seemed that we ought to fix upon some simple, uniform way of doing this. There were one or two operations which appeared to work satisfactorily. One of these at present claiming considerable attention was the Sluder operation, and now we had another in the procedure described by Dr. Sheedy. The complete removal of the tonsils, *i.e.* tonsillectomy, should be done exceedingly carefully and in a manner which should reduce the subsequent palatine deformities to a minimum.

Dr. J. Alexander McIsaac said that both in children and adults he never did a tonsillectomy except under gen-

eral anesthesia, so that he could have complete control of his patient. In his experience, where a tonsil caused trouble from inflammation and disease he found that it was very adherent to the surrounding tissues. Therefore, the best technique was the one which would cause the least possible trauma in removing it. He had found that the best method was to dissect both the anterior and posterior pillars carefully away from the adherent capsule, and then to dissect the capsule from the superior constrictor muscle; at the same time directing pressure against the capsule. Finally, the wire snare was employed to complete the operation. In the hands of another physician he had seen a secondary hemorrhage follow the use of the snare without the preliminary dissection. He had had no experience with the method described by Dr. Sheedy in his paper.

Dr. Sheedy, in closing, said that Dr. Simpson's remarks applied more particularly to children. The cases referred to in his paper were entirely in adults. With the exception of one or two instances, in a very large number of cases, he had not seen unsatisfactory results in children when the operation was carefully and properly performed. In the various cutting and dissecting operations we necessarily had cicatrical tissue, and from this there naturally followed the contractions resulting in the abnormal conditions, especially in the pillars, of which he had spoken. There could be no question that tonsillectomy, as heretofore performed, was a major operation, and one which should always be done in a hospital, where proper assistance and appliances were ready at hand, and where the patient could lie up for a day or two and have suitable after-care. The Sluder method was intended to do away with the difficulties associated with the work as now performed, but injury to the anterior pillar was almost inevitable under this procedure. The evertion operation, as he had described it this evening, was so simple a surgical procedure that any man with any surgical experience could do the work with safety, and if the snare were tightened slowly there would be no after-hemorrhage with which to deal. This statement applied to the operation in children as well as adults, and whether the operation were done under a local or a general anesthetic.

## State Medical Licensing Boards.

### STATE BOARD EXAMINATION QUESTIONS.

Tennessee State Board of Medical Examiners.

*May, 1912.*

(*Concluded from page 597.*)

#### PRACTICE.

1. Define chlorosis. In what sex does it most frequently occur? Define leukemia. Name the organs and glands involved in the pathology of leukemia.

2. Define acute peritonitis. Give the causes. Briefly give a treatment, preventive and curative.

3. Define acute enterocolitis. Name the age and predisposing causes which produce this disease. Give treatment, preventive and curative.

4. Define fever, pyrexia. What is an antipyretic? Name some antipyretics you would use in fevers.

5. Define tuberculosis. Name some of the common forms of it. Give briefly a general treatment for pulmonary tuberculosis.

6. Give a clinical picture of an acute attack of appendicitis (typical). Give treatment.

7. Define locomotor ataxia. Name the structures involved in the pathology. Give general symptoms.

8. What is meant by the term, "neurosis"? Is heart palpitation a neurosis or an organic disease? Define tachycardia, brachycardia. What is arteriosclerosis?

#### OBSTETRICS.

1. Give in detail your management and duties in a case of labor, from its inception until the patient is convalescent.

2. Give the physiology of fecundation.

3. What is the placenta? From what is it formed? What is its structure and what its functions?

4. What structures enter into the formation of the pelvic floor?

5. Name five of the most important signs of pregnancy and state the dates when they are most available.

6. Describe the various things you would suspect in a case of pregnancy with frequent or continuous hemorrhage.

7. What is your idea of the use of anesthetics in labor; what would you use? Why? What are some of the dangers from their use?

8. Under what conditions may shortening of the round ligament be justifiable? Describe the operation.

#### SURGERY.

1. State in detail how you would perform suprapubic cystotomy for the removal of a stone from the bladder.

2. Name five of the principal complications of gonorrheal urethritis in the male.

3. How would you prepare a patient for an anesthetic and what examination of patient would you make?

4. Give the signs of surgical anesthesia. Complications likely to occur during anesthesia. How would you combat them?

5. What is an aneurysm? Give symptoms and treatment.

6. What is acute osteomyelitis? Give causes, symptoms, and treatment.

7. Give in detail the surgical method for the removal of the fluid in a case of ascites.

8. What are the indications for castration? Give in detail the method of operation.

### ANSWERS.

#### PRACTICE.

1. *Chlorosis* is an anemic condition of unknown origin, and marked by a reduction of the hemoglobin. It occurs most frequently in females.

*Leukemia* is a condition in which the white blood corpuscles are increased and changes are found in one or more of the following: Bonemarrow, spleen, lymphatic glands.

2. *Acute peritonitis* is acute inflammation of the peritoneum. Causes: Bacterial infection, extension of inflammation from neighobring organs, penetrating wounds, or perforation of an ulcer in the stomach or intestines.

*Treatment* is operative; but pain may be lessened by morphine (used judiciously); ice or warm applications may be used; subcutaneous injection of saline solution is of value in combating shock or collapse. Rest is imperative; and the causative factors should be attended to.

3. *Acute enterocolitis* is an acute inflammation of the lower part of the ileum and of the colon. It often occurs in infants. *Causes*, are: Improper feeding, bacteria, debility; and warm weather and teething are said to predispose. *Treatment* consists in giving proper food *beforehand*. With the onset of the disease, a simple purge, lavage of stomach and colon, and proper food are indicated. Bismuth, and Dover's powder may check the diarrhea.

4. *Fever* or *pyrexia* is a condition or disease in which the bodily temperature is above normal.

An *antipyretic* is an agent used to combat fever. Such are: Cold water, quinine, phenacetin, aconite.

5. *Tuberculosis* is a disease characterized by the formation of tubercles and caused by the presence of the *Bacillus tuberculosis*. It may attack the lungs, joints, lymphatic glands, meninges, peritoneum, or any other tissue or organ of the body. *General treatment for pulmonary tuberculosis* consists in fresh air, rest or mild exercise, plenty of sunlight and good food (eggs, milk, fresh vegetables); medicines used are castor oil, creosote, tuberculin, hypophosphites, arsenic. Symptoms are treated as they arise.

6. *Acute appendicitis* is characterized by sudden onset with pain in the right iliac fossa, moderate or high fever, nausea, vomiting, constipation, tenderness over the abdomen (chiefly in right iliac fossa), pulse rapid in proportion to the fever, rigidity of the right rectus abdominis muscle, the patient lies on his back with the right leg semi-flexed. *Treatment* is surgical; a competent surgeon should be called in at once. Temporizing is often fatal.

7. *Locomotor ataxia* is "an affection characterized clinically by sensory disturbances, incoordination, trophic changes, and involvement of the special senses, particularly the eyes. Anatomically there are found degenerations of the root-fibers of the dorsal columns of the cord, of the dorsal roots, and at times of the spinal ganglia and peripheral nerves. Degenerations have been described in the brain, particularly the cortex cerebri, in the ganglion cells of the cord, and in the endogenous fibers of the dorsal columns." (Osler.)

*Symptoms:* Loss of coordination; characteristic and unsteady gait; tendency to stagger when standing up with feet together and eyes closed; sharp and paroxysmal pain, called *crises;* girdle sensation; loss of knee-jerk and other reflexes; Argyll-Robertson pupil. The *diagnostic features* are: A slow onset; the loss of the patellar reflexes; Argyll-Robertson pupil; lightning pains; incoordination.

8. A *neurosis* is a nervous disease which is functional and not dependent upon a lesion. Heart palpitation is a neurosis. *Tachycardia* is rapid heart-beat. *Bradycardia* is slow heart-beat. *Arteriosclerosis* is an overgrowth of the intima of an artery, with degenerative changes in the media, and general thickening and loss of elasticity of the arterial walls. And see above, PATHOLOGY, *Question* 1.

OBSTETRICS.

1. *The patient* should receive a full bath before labor begins and all bed-clothing and personal clothing should be clean. If there are any pathological discharges from the genitalia, the vagina should be thoroughly scrubbed with tincture of green soap and hot water, followed by a mercuric chloride douche (1:2000); this followed by a douche of sterile water. The physician's hands should be scrubbed for 10 minutes with tincture of green soap and hot water, followed by alcohol, and immersion in mercuric chloride (1:1000). All instruments should be boiled for 10 minutes or immersed in mercuric chloride (1:000) for half an hour. Examinations should be made frequently to determine the position, presentation, size of the fetus, etc.

*During the first stage* a rectal enema of soapsuds with turpentine (5i) should be given, and when the os is dilated to the size of a silver dollar, the patient should be placed in bed, lying upon the side toward which the fetal back looks. If the pain is severe, chloral hydrate (gr. 15) may be given every half-hour for 3 doses.

*During the second stage,* examinations should be made every 10 or 15 minutes. In multiparæ, the membranes may be ruptured with the finger or with some aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent laceration of the perineum by making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the mother's side with its face turned away from the maternal discharges.

*During the third stage,* 5i of the fluidextract of ergot is administered and irritation of the uterus by friction through the abdominal wall is practised for 10 to 15 minutes. If the placenta is not expelled by this time, the uterus is firmly grasped between the thumb and four fingers and compressed. Firm pressure is then made from above downward and backward in the direction of the pelvic canal. This usually causes delivery of the placenta. A vulvar pad of salicylated cotton and carbolized gauze and an abdominal pad and binder are then applied.—(Gould and Pyle's *Pocket Cyclopedia.*)

2. *Fecundation* is the result of the meeting of a live and healthy spermatozoon, with a live and healthy ovum, in a suitable medium (generally the Fallopian tube). During coitus the seminal fluid is ejected into the upper part of the vagina and against the cervix of the uterus; the spermatazoa enter the uterine cavity (either by the suction of the uterus or by their own vibratile motion) and so on to the Fallopian tube. Several spermatozoa may surround an ovum, or even pierce the perivitelline space; but only one spermatozoon enters the vitellus. This spermatozoon loses its tail; and its head becomes the male pronucleus. The male pronucleus and the female pronucleus now fuse together, and fecundation is completed.

3. At full term the *placenta* is a soft, spongy mass, roughly saucer-shaped, from six to nine inches in diameter, about three-quarters of an inch in thickness at the central point, and weighs about one pound. It is *formed,* partly from the mucous membrane of the uterus, and partly from the chorionic villi. Its *functions,* are: (1) To supply nourishment to the fetus; (2) to act as a respiratory organ for the fetus; (3) to act as an excretory organ for the fetus. Its *usual location* is on the anterior or posterior wall of the uterus, near the fundus.

4. *The pelvic floor* is composed chiefly of fascia, muscles, and connective tissue. Its superior surface is lined by peritoneum. Next below, and in close contact with the peritoneum, comes the "internal pelvic fascia." Immediately below the internal pelvic fascia are two thin muscles: The *levator ani* and the *coccygeus.* Below these muscles the pelvic floor is further strengthened by the *perineal fascia.* Its posterior portion consists of a single layer, while its anterior part is divisible into three layers. Within these latter layers are lodged the pubic vessels and nerves, and the superficial muscles of the perineum. These muscles are the *constrictor vaginæ,* the *sphincter ani,* and the *transversus perinei,* and to these structures must be added the integument and the very numerous interstitial layers of elastic connective tissue, which latter weld the parts together and add strength and elasticity to the whole fabric.—(From King's *Obstetrics.*)

5. *Five important signs of pregnancy:* (1) Hearing the fetal heart sounds, from the eighteenth week onwards. (2) Palpation of the fetal parts; during the last four months. (3) Detection of the movements of the fetus; during the last three or four months. (4) Hearing the funic souffle; during last two months. (5) Hegar's sign; from the second month onward.

6. Frequent or continuous hemorrhage during pregnancy might be due to: Placenta prævia, or premature separation of the placenta, or to apoplexy of the decidua or placenta. Hemorrhage during pregnancy may also indicate abortion or ectopic gestation.

7. ANESTHETICS are used in labor to lessen suffering produced by labor pains; to lessen the pain attending obstetric operations; to relax the uterus when its rigid contraction interferes with version; to promote dilatation of the os uteri; to reduce excessive nervous excitement which may interfere with progress of early stage of labor; to relieve eclamptic convulsions and mania; in cases of uterine inversion to relax the constricting cervix and so facilitate replacement; in bipolar version to lessen pain of introducing the hand into vagina; in precipitate labor to suspend action of voluntary muscles and retard delivery; in all cutting operations upon the abdomen; and sometimes in sewing up a lacerated perineum when many sutures are required.—(From King's *Obstetrics.*)

Chloroform is most frequently used; probably because chloroform is easier to administer, does not require cumbersome apparatus, allows of the patient being partially or completely anesthetized as may be necessary.

*Dangers:* It lessens the efficiency of the uterine contractions; it predisposes to postpartum hemorrhage; and, if given too freely, may be followed by headache, nausea, and vomiting.

8. *Shortening of the round ligaments is indicated in:* Retroversion of the uterus uncomplicated by adhesions, tumors, or inflammation of the adnexa.

*Alexander's operation:* "The pubic hair is shaved off and skin and vagina disinfected. The uterus is replaced and a glass stem with attached silk thread introduced into its cavity. A narrow Hodge pessary is placed in the vagina. Next, the patient's legs are extended. The operator stands on the side opposite to the ligament to be shortened; he locates the pubic spine, which is the leading landmark during the whole operation, and makes an incision from 1 to 3 inches in length through the skin over it, in the direction of the slit between the pillars of the external inguinal ring. Its length must be proportionate to the amount of adipose tissue present, but it should, if possible, not extend beyond the hairy portion of the mons Veneris, as then, after the hairs grow out again, the cicatrices will be entirely hidden. Next, the subcutaneous fat and the superficial fascia are divided in the same direction, exposing the glittering, satin-like pillars of the external ring, which is situated above and a little outward of the spine of the pubis and can be felt at the bottom of the wound. It is well to dissect the aponeurosis of the external oblique abdominis muscle, so as to see not only the pillars, but the intercolumnar fascia extending between them. During the incision several small arteries will be severed and must be clamped. In the external inguinal ring is seen a lump of fat which contains the ligament. This whole mass is grasped with an artery-forceps and drawn in the direction of the vulva. The genital branch of the lumborcrural nerve is seen as a fine white cord in front or to one side of the ligament. If it is in the way, it may be cut, but generally it suffices to push it aside. From the ligament extend a number of sinewy threads to the sides of the inguinal canal, which must be severed. Sometimes the peritoneum is invaginated and forms around the ligament a sheath, which must be stripped back with the nails of the fingers. When the isolated white tendinous ligament peels readily out from the canal, the wound is covered with iodoform gauze or sterile gauze; the operator takes his position on the other side and treats the second ligament in the same way. Before

fastening the ligaments he should pull both forward and ascertain, through the abdominal wall or the vagina, that the uterus is tilted forward. He should then slacken them from ¼ to ½ inch, in order to avoid undue strain on them and the formation of a hernia. They are fastened by passing three sutures of chromicized catgut through them and both pillars on each side, the last one comprising some of the tendinous tissue in front of the pubic bone. When the sutures have been tied, the superfluous piece of the ligament, which will measure from 2 to 4 inches, is cut off. The superficial fascia is closed with running suture of plain catgut, and finally the skin wound is closed with two or three sutures of silkworm gut. The two wounds are dressed with one piece of iodoform gauze, guttapercha tissue, and plain gauze, kept in place by a double spica or straps of rubber adhesive plaster. At the end of a week the superficial sutures are removed. The patient should remain in bed three weeks."—(Garrigues' *Gynecology.*)

SURGERY.

1. *Suprapubic cystotomy:* "The patient is prepared as for any abdominal operation, including shaving of the pubes. The capacity of the bladder should have been previously tested, and at the time of operation the bladder should be irrigated and filled with boric acid solution, or, as some surgeons prefer, filled with air. A catheter is tied about the penis, in order to prevent the escape of fluid, and the patient placed in the Trendelenburg position. These maneuvers displace the vesical fold of the peritoneum upwards, and thus permit extraperitoneal exposure of the bladder. A three-inch incision is made in the median line from the symphysis pubis upwards, the prevesical fat separated, and the bladder recognized by its longitudinal muscular fibers and its globular form. Two sutures are passed through the bladder wall to act as tractors and a longitudinal incision made between them. Stones may be removed with the fingers, forceps, or scoop. If the bladder is not infected, the wound may be closed by two layers of Lembert's sutures of catgut and the incision in the soft parts approximated, leaving space for a small gauze drain running down to the bladder. If this course is followed, a retention catheter should be passed into the bladder through the urethra. If the bladder is infected, the wound in its wall may be sewed to the fascia, or it may be closed with catgut sutures which invert it about a rubber tube, several of the sutures passing through the tube. The tube should be long enough to syphon the urine to a receptacle beneath the bed."—(Stewart's *Surgery.*)

2. *Five complications of gonorrheal urethritis:* Epididymitis, cystitis, prostatitis, vesiculitis, and gonorrheal rheumatism.

3. *"The preparation for anesthesia,* in cases requiring a major operation in which there is no emergency, should extend over two or three days, during which time, in addition to the special preparations for the operation itself, the patient should be carefully examined, particularly for the presence of disease of the heart, blood vessels, lungs, and kidneys. The condition of the nose, throat, and mouth should be known, and in many cases a careful examination of the blood will be required. The bowels should be moved by a laxative, and an enema administered in the morning of the operation. The diet should be light and easily digestible. No solid food should be given on the day of operation, although a cup of tea, coffee, or consomme may be given not less than six hours before the time of anesthesia. In the feeble and exhausted purgation should be avoided, and stimulating or nutritive enemas may be continued until within a few hours of the operation. Just before operation the patient should pass urine, or, if necessary, be catheterized. If the patient be a woman, the hair should be braided and done up in a cap or towel. Artificial teeth or other foreign bodies should be removed from the mouth, and the lips and nostrils greased, especially if chloroform is to be used. The patient should be suitably protected from cold. In cases of intestinal obstruction the stomach should be washed out previous to the administration of the anesthetic, in order to prevent sudden death from inundation of the lungs with vomited fecal matter."—(Stewart's *Surgery.*)

4. *The signs of surgical anesthesia,* are: Absence of conjunctival or corneal reflex, deep and rythmical breathing, muscular relaxation, and insensibility to pain.

*Complications that may arise:* (1) Vomiting; this sometimes requires more of the anesthetic, and sometimes a few breaths of air. The mouth be cleared of the vomitus, and the patient's head turned to one side to allow the vomited matter to escape. (2) *Syncope;* stop the anesthetic, lower the head of the bed, make traction on the tongue, start artificial respiration, and give a hypodermic of strychnine. Apply heat, give an enema of hot salt solution. (3) *Forgetting to breathe;* remove the inhaler, and make traction on the tongue. (4) *Swallowing the tongue;* pull the tongue forwards.

5. An *aneurysm* is a pulsating sac containing blood, and communicating with the lumen of an artery.

*Symptoms:* A soft, elastic, pulsatile tumor in the line of an artery; pulsation ceases if pressure is made on the artery above the tumor, and reappears on relaxing the pressure; similar pressure on the artery below the tumor, causes it to enlarge; a systolic bruit can often be heard over the tumor; the pulse below an aneurysm is weaker than the corresponding pulse in the opposite limb; there may be pain, and weakness of the part affected.

*Treatment:* Rest in bed; restricted diet (both solid and liquid); iodide of potassium in doses of gr. xv to xx; hypodermic injection of gelatin; pressure; ligature, various methods (Antyllus, Anel, Hunter, Wardrop, Brasdor); extirpation of the sac; and aneurysmorrhaphy.—(Matas' operation).

6. *Osteomyetitis* is inflammation of the bone and marrow; the term is often used now for inflammation of bone.

It is *caused* by infection, the bacteria gaining entrance either through a wound, or by extension from neighboring tissues, or they may be brought by the blood.

*Symptoms:* Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present.

*Treatment* consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

7. *To remove the fluid in a case of ascites:* "A puncture should be made either in the median line midway between the umbilicus and the symphysis pubis, or midway between the umbilicus and the anterior superior spine of the ilium. The instrument used is a trocar and cannula or the needle of an aspirator. The depth to which it shall be allowed to penetrate is regulated by the finger placed upon its side, and it should be plunged in sharply, without a preliminary incision, at the selected point, which should be absolutely flat upon percussion. As there is a possibility of syncope occurring during the operation, in consequence of the withdrawal of pressure, it is prudent first to pass a broad, many-tailed flannel bandage about the abdomen, crossing its ends behind, so that an assistant standing at each side can draw upon them and tighten the bandage as the liquid escapes. It is usually sufficient, however, to have an assistant make steady pressure with one hand on each side of the abdomen. During the operation the patient should be seated or inclined toward one side."—(Stimson's *Operative Surgery.*)

8. The *indications for castration* are: Malposition of the testicle, tuberculous disease, old standing hematocele, cancer, or other tumors, and chronic enlargement of the prostate gland.

"The operation is conducted as follows: The pubes and perineum having been previously shaved and purified, the surgeon, standing on the same side of the patient as the organ to be removed, makes an incision down to the testis. If large and adherent to the scrotal tissues, the incision must necessarily involve the scrotum, but wherever practicable it is wise to avoid the scrotal integuments, making the incision over the cord. It should always extend upwards as far as the external abdominal ring, so as to enable the structures of the cord to be divided high up—a most important matter in tuberculous and malignant disease; the inguinal canal can then also be closed, if necessary. The testis or tumor is enucleated from its surroundings, and the cord isolated and divided as high as possible, after transfixing and securely ligaturing it with silk. The stump should not be allowed to slip back into the canal until all bleeding has completely stopped, and it has been suggested that the cut end of the vas should be touched with pure carbolic acid as a precautionary measure. All bleeding points in the scrotum are now secured by ligature, and these may be numerous; the wound is closed by sutures, a drainage-tube being inserted in the scrotum, and by choice coming to the surface at the upper end of the wound—that is, as far from the perineum as possible."—(Rose and Carless' *Surgery.*)

### THE MONTESSORI METHOD FROM A PHYSICIAN'S VIEWPOINT.

By GEORGE W. JACOBY, M.D.,

NEW YORK.

Six years have passed since Dr. Maria Montessori founded her first house of childhood (Casa dei Bambini) in Rome, which because of her special educational method, at once achieved a decisive success. This method does not merely touch upon single points of the theory and practice of pedagogy but penetrates so deeply into the science of education and is of such revolutionary nature that all cultural peoples are to-day discussing whether the existing methods of instruction and education ought not to be developed further by amalgamation with the Montessori method, or whether our entire kindergarten and school system must not be reconstructed upon a different basis.

The possibilities that will confront us in this regard will be a matter for later consideration; for the moment let it suffice to recognize the fact that here in America pedagogic interest has become focused upon this question. To *McClure's Magazine* belongs the credit of having first directed the attention of the American public to the Montessori method. In May, 1911, Josephine Tozier wrote the first article on the subject, and that gave the impetus for the writing of several excellent dissertations since. Last year Anne E. George gave us a translation of Montessori's best known work, "Il Metoda della Pedagogica Scientifica," a book which, together with the "Antropologia Pedagogica" of the same author, must constitute the sole authentic source of all information regarding the method in question. Furthermore, Maria Montessori herself has directly addressed the American public in *McClure's Magazine*.

The works just cited have aroused the interest of the entire American pedagogic world to such an extent that a lively exchange of ideas, in the press and upon the lecture platform, is daily taking place. In fact the literature upon this subject has grown, in this brief space of two years, to the proportions of a small library, and the interest in the subject, even among those whose attitude is one of challenge or merely one of expectation, is steadily augmenting. An astonishing fact is that, so far as I have been able to follow the literature on the subject, this discussion has been carried on by pedagogues only, and with the exception of a short article by S. H. Brown, in the Medical Record, nothing has been published by any physician in regard to this method. Still I think it cannot be contradicted that a method of instruction and education, originated by a physician, built up entirely upon psychologic-physiological principles, originally elaborated for medical purposes, and which has efficaciously forced on us a recognition of the dependence of pedagogue success upon a knowledge of physiological and pathological processes of life, is one which demands more or less extended medical consideration.

For me personally, there exists yet another incentive for such consideration, because during a stay of a couple of months in Rome last Spring I had the opportunity of becoming personally acquainted with Mme. Montessori and of studying her method amid the surroundings for which it was elaborated. From what I have already said, it will be seen that my task here will necessarily be a restricted one, for I am relieved from the obligation of systematically and exhaustively unfolding the theory and practice of the Montessori method. Nearly everything that can be said about this has already been amply emphasized in *McClure's Magazine* and elsewhere

I am further restricted in the elucidation of the fundamental principles by the fact that their purely pedagogic aspect has already been enlarged on in lectures and published articles and, more especially, in the adverse conclusions formulated by the Teachers' College in August, 1912. Only in so far as the pedagogic aspects are inseparable from the medical points of view, will they be referred to by me.

In thus discussing the Montessori method from a purely medical standpoint, I would sum up the total impression which I have derived from it in the words, "The better is the enemy of the good."

A method of training and instruction which, premising equal average talent, enables children of from four to five years of age to occupy the same plane of mental development as children who have already gone to school for two or three years, a method which enables psychically deficient children to compete with normal children of equal age, a method which, without the employment of measures of restraint, is able to effect model discipline, a method, finally, which makes of the teacher essentially an observer and allows the child itself, controlled only by the teaching material, to gain correct notions of the outer world entirely through its instinct for occupation and investigation; such a method seems to me to fulfill all the demands which the steadily augmenting intensity of the struggle for existence of our times must make upon the training of the adolescent generation. Only he can successfully compete in the struggle for existence who has adapted himself to his environment, who is prepared for the changing requirements of life through which he is confronted now with one task, now with another. In order to render the child mentally and physically fit for the struggle for existence, it is not sufficient to equip it with a certain sum of knowledge and acquirements. Nor does a training suffice which merely will make of the child a good grown up. Our times demand people of strong will, people who are able to maintain themselves in the rank in which fate has placed them.

Education, therefore, must strive above all else to arouse that initiative, that mental spontaneity, which will enable the child to think and to act independently. It is just this which is achieved better through the Montessori method than through any other educational system. As a matter of fact, the Montessori children, upon their admission to the primary school, have something which the Froebel children do not possess. Among other things, the conclusions of the Teachers' College say, the principle of free self-development of the child is not new, Rousseau already having advocated this principle and it having been espoused in America particularly by Prof. Dewey. This is quite true. The same idea may even be found expressed in Herbert Spencer's book on "Education," in which he says: "In education the process of self-development should be encouraged to the fullest extent. Children should be led to make their own investigations and to draw their own inferences. They should be *told* as little as possible, and induced to *discover* as much as possible."

Whether Dr. Montessori had any knowledge of these words I do not know, and it is entirely immaterial whether she did or not, since it is only the heuristic method of finding for one's self which is common to the theories of Spencer and Montessori. What does matter much, however, is whether we say, with Spencer, that children should be "induced" to discover, or whether we agree with Montessori that children in themselves possess the innate proclivity to discover and that the educator should remain passive and allow this instinct to develop in an unhampered way. Dr. Montessori, in fact, goes so far as to allow the child to busy itself all day long with any one thing which may please it and hold its interest.

While the Froebelian method requires the children to occupy themselves in groups, now in one way, now in another, Montessori looks upon it as a mistake to interrupt the child's propensity for investigation so long as a certain object holds its interest and rivets its attention. In this Dr. Montessori starts from the correct idea that it is the endeavor of the child to recognize an object from all points of view, that its interest will pall of itself as soon as this endeavor has been satisfied, and therefore that so long as this interest is present, it should not be interrupted, for such an interruption, suppressing as it does the child's endeavor and effort, is equivalent to a restraint of development. Certainly these ideas are not new. Mme. Montessori again and again lays stress upon the potent influence which the writings of Séguin have exercised upon her. But no one can say that these ideas have been adopted by her unaltered. On the contrary, she has so modified them that, in their present form, they are in full accord with the demands of physiological psychology. To her is due the credit of first having obtained for these ideas no mean amount of recognition, and of having forced upon the pedagogic circles of all countries the consideration and discussion of a method of instruction and education which is built up entirely upon the basis of physiological psychology.

The feeling that reform of some kind in our present method of education is necessary seems to permeate the entire atmosphere. Before me as I write is Edmond Holmes' "What Is and What Might Be in Education." Without knowing Dr. Montessori and without having heard of her work, Holmes in London has arrived at conclusions very similar to those of the founder of the "Casa dei Bambini" in Rome. He also is an advocate of free self-development of the child and of the widest individualization. In "What Is" Holmes, by examples taken from actual life, shows the consequences which will ensue when the natural impulses or instincts of the child are repressed or abused. In "What Might Be" he introduces to us *Egeria,* a teacher in a school in *Utopia,* all whose efforts are directed toward allowing the natural impulses of the child to develop themselves in an unhampered way. For the children of Egeria's school, there exists neither punishment nor reward. Notwithstanding that they are subjected to no constraint of any kind, that no threat of punishment frightens or intimidates them, no promise of reward allures them or arouses their ardor, the children thrive and observe most model discipline.

Mental cripples who by rote have acquired a mass of undigested knowledge and who through the principle of punishment and reward have been trained to a "mechanical obedience"—these are the fruits of the school "as it is." Mentally alert children, full of live interest in the things which surround them, not crammed with mere memory knowledge, but equipped with that independence of thought and judgment which at the given moment is able quickly to find itself, and which through free obedience makes the calls of unlovely egotism subordinate to the interests of the many—these are the fruits of the school "as it might be." Mr. Holmes has told me his Egeria and his Utopia were not, as I assumed them to be, the products of his imagination. Both teacher and school were the actualities of an English village and in his book he informs us that the type of education which flourished in the soil and atmosphere of Utopia developed children of "activity, versatility, imaginative sympathy, a wide and free outlook, self-forgetfulness, charm of manner and joy of heart." Whoever has seen a class of Montessori infants would regard those words as a forecast of their future.

"The better is the enemy of the good"—therein lies the root of all cultural progress. Not to accord recognition to a better idea because we do not wish to relinquish a good one signifies arrest of progress. This is as true in pedagogy as it is anywhere else. So long as this science was under the bane of that psychology known as speculative, which, notwithstanding its most skillful construction, took hardly any cognizance of the true mental life of the child—so long could there be no progress. Pedagogy could become rational only when physiological psychology furnished to it an exact basis for observing the child's mind, and pathological psychology, taught the pedagogue how to differentiate the healthy mind from that which was diseased.

Without exact knowledge of normal and pathological vital processes, pedagogy necessarily fell into grave errors as soon as it was obliged to occupy itself with children who in any way deviated in their powers of conception, their emotional life, and their will power, from that imaginary type designated as "normal." Inasmuch as speculative psychology was entirely unfamiliar with the mental life of these children, it follows that they could not be trained by the pedagogy which was the outgrowth of that psychology; and because such children were unable to adjust themselves to that pedagogic standard adopted for the "normal type" they were treated as insubordinates, often with severity which bordered upon brutality. Of course under such treatment

matters could only grow worse, and as a result these unfortunate children often became the victims of complete neglect. Conditions remained thus until physiological and pathological psychology, after ceaseless endeavors, succeeded in finding the key to the mental life of these children and thereby furnished the proof that pedagogic success depends essentially upon a precise knowledge of these laws which, under physiological as well as under pathological conditions, governed the development of the child.

Every method of training and instruction which leaves these laws of development unconsidered, is wrong. Any method which accords them proper recognition is right. Which method is right and which wrong may easily be deduced from the fact that in the reign of a pedagogy built upon the basis of speculative psychology, there was a dwarfing of mental attributes, which, under the sway of the physiological method, were brought to a brilliant development.

We must not take the position that a healthy mind will think correctly without knowledge of the laws of logic, for, although we may unconsciously do that which is correct, science must not count upon such eventualities. This topic is of such interest and approaches so closely to the root of the Montessori method, that I cannot refrain from attempting to show, by a brief historical retrospect, the influence which the science of medicine has exerted upon that of pedagogy.

In so doing we encounter four names, each of which represents a milestone in the development of the physiological method. Above all there is the French physician Itard, who through his successful treatment of the "savage of the Aveyron" made for himself a name of world renown. This "savage" was simply a weakminded person who either had been abandoned in the forest by his relatives, a means of disposing of undesirable children not infrequent in those times—or had lost himself in the woods of the Aveyron in southern France, and there led a poverty-stricken existence. When he was found in the year 1801, he had sunk almost to the level of a beast which, considering that this unfortunate creature had for years not seen or come in contact with any human being, was not surprising. Itard most humanely interesting himself in this "savage," devoted six years of his life to arousing the man from his mental decadence and even though he did not finally succeed, he at any rate was able to give to him a certain amount of knowledge, through which he was helped to support himself by useful work. Such a thing was at that time an entirely unheard of occurrence, and the interest Itard aroused with his "savage," whom he had transformed into a well behaved being, surpassed all description.

In order to understand this, we need only consider the notion of those times that two things were unalterably proven. The first accepted fact was the educational incapability of idiots. Because of that belief no person seriously thought of improving weak-minded children through training and education. It was recognized as an accepted truth, secondly, that not only the adult insane but also idiotic children were possessed by the devil. How genuine that belief was is shown when it is recalled that so eminent a man as Luther, on seeing a very unclean, malicious and voracious idiotic child, proposed to take the little one into the water and chance its being drowned.

Encouraged by Itard's success, Ferrus, in 1828, opened a special school for cretins in the Bicêtre in Paris, which in 1839 was followed by another under Voisin's direction. Voisin's successor was Edouard Séguin, whose name is connected with the second important step towards the attainment of a method of treatment, founded upon physiological psychological principles, for mental weakness in children. As we know, Séguin emigrated in 1848 to America. Here he was superintendent for a long time of the Pennsylvania Training School, as well as of the Massachusetts Institution for the Feebleminded at Waverley. He died as a practising physician in New York City, in 1880. Séguin, as a pioneer, elaborated a system of medical pedagogy, and in a book entitled "Traitement Morale, Hygiène, et Éducation des Idiots et des Autres Enfant Arriérés," gave expression to his views. This book was followed twenty years later (1866) by another, entitled "Idiocy and Its Treatment by the Physiological Method." Both books have been translated by Dr. Montessori into Italian, and have formed, so to speak, the substructure of her method.

The name which represents the third forward step in the progress of the physiological method is that of Guggenbühl, who in 1836 began devoting his time to the cure of cretins, and for this purpose established an institution upon the Abendberg near Interlaken, which soon became renowned in all parts of the world. The visitors who poured in from all sides became convinced, as a result of what they saw there, of the possibility of educating *all* feebleminded persons and returned home imbued with enthusiasm for the foundation of similar institutions in their own countries. Unfortunately, the enthusiasm for Guggenbühl and his activities lasted barely twenty years. Naturally he had failures, some of which were due to the fact that he undertook frequent and long journeys during which his pupils were left in the hands of incapable and ignorant persons. He was then accused of promising more than he was able to do. Little by little his friends and patrons left him, and in 1860 the institution had to be closed. Three years later Guggenbühl died in solitude.

The disappointment experienced by the supporters of Guggenbühl must not be attributed to any shortcomings of the physiological method, but was essentially dependent upon the fact that Guggenbühl had no clear understanding of the various forms and causes of feeblemindedness, and was not able to discriminate between the various degrees and kinds of infirmity on which depends the incapacity of the feebleminded for educational equipment. The same may also be said of Séguin. Both physicians started from the correct premise that, as the mental abnormalities of childhood are connected with bodily defects, abnormal children require special pedagogic treatment. But to their way of thinking, there existed only one class of feeble-minded children, which by Séguin was termed "idiots" and by Guggenbühl "cretins." They could not know that idiocy and cretinism were dependent upon entirely different causes. The relation which the functions of the thyroid gland bears to mental development has been recognized only in recent times, and only through that recognition has the nature of cretinism become clear. Similarly, our knowledge of the changes in the brain which are characteristic of idiocy and our knoweldge of the methods which enable us to estimate the capacity for training possessed by defectives and deficient children, are of recent acquisi-

tion. Séguin neither knew how to differentiate between true feeblemindedness dependent upon congenital brain defects or upon defects acquired early in life, nor did he understand that mental backwardness may be simulated—for example by adenoid vegetation of the nasopharynx. Finally, also, neither Guggenbühl nor Séguin possessed that diagnostic discernment which would have enabled them to recognize the large and varied horde of mental deficiencies which modern investigations have shown to be dependent not upon organic defects but upon functional nervous disease and which, being in great part due to neuropathic taint affecting the intellectual development, the emotional life and manifestation of the will, occupy a position midway between health and disease.

This lack of knowledge, not due to any fault of their own but to the state of science at the time in which they lived, could not help but result in the mistakes which were made by Séguin and to a greater extent by Guggenbühl, mistakes which caused the merits of these two men to be so soon forgotten. To Madame Montessori belongs the credit of having, so to say, rediscovered Séguin and having disinterred his neglected work. When Guggenbühl removed his cretins and the children whom he believed to be threatened with cretinism, from the swampy lowlands of the valleys into the pine air of the Abendberg, he acted according to physiological principles. His aim was to take them from the noxious influences which were the cause of their trouble and which, in the opinion of the times, consisted in a saturation with moisture of the stagnating air of the valleys. Undoubtedly among these children there were many in whom the thyroid gland was still capable of functionating, at any rate, partially, and in whom the more favorable conditions of life to which they were removed produced an improvement in thyroid secretion thus causing at least an amelioration of their disease. It was such cases that led to exaggerated expectations which could end only in disappointment. In other children the thyroid gland was entirely absent or its function had been totally eliminated, while in still others it was a question not of cretinism but of weakmindedness with brain defects. In all such cases, of course, the removal to the Abendberg could be of no avail.

Séguin's failures are also to be ascribed to the fact that he was unable to individualize properly, that he did not consider with care the degree of cultural capability, which varied according to the nature and seriousness of the mental disorder. Nevertheless, even to-day, some of Séguin's principles may be looked upon as exemplary. This may be said of the method which he employed in the development of sensory activity, the basis of all mental activity, and also of perseverance, a quality which he considered one of the most important attributes of the educator, particularly in those cases in which certain work is demanded, for which the pupil would be perfectly competent were it not for a marked weakness of will power which prevents him from accomplishing the allotted task. In his "traitement" Séguin himself gives a very remarkable example of this perseverance. He tells of an intensely excited, restless, constantly moving idiot, whom he pacified by sitting opposite him, holding the legs of the child with his knees, with one hand holding the hands of the child, and remaining in this position for five weeks, excepting only the time devoted to eating and sleeping. True, this mechanical fixation is not actually a means of education but merely an adjunct of training. Still the example of Séguin teaches us that perseverance, aided by the power of personality, will bring about results which at first impression we would believe to be impossible.

It seems to me no better example of perseverance and endurance can be found than is furnished by Dr. Montessori herself. It is she who represents the fourth and at the same time the newest stage in the development of the physiological method.

Without considering what effect her ideas would produce, she gave up years in a spirit of complete self-sacrifice, to the theoretic and practical study of the feebleminded. In order to be able to weigh every word and gather Séguin's true spirit, she herself translated the two volumes of his writings into Italian; after graduation she again attended lectures upon psychology and pedagogy, determined to found her work upon a scientific basis. Then, unknown as she was, except perhaps for the fact that she was the first woman to have been graduated from the medical faculty at Rome, she appeared before the public with certain practical experiments and ideas—call them novel or not as you will—and at once achieved a far-reaching success.

Whether the principle for which Montessori battles, the free individual self-development of the child, has found a specially favorable soil in the despotic atmosphere which still rules the Italian schools to a great extent, I cannot say. Nor can I decide whether her most marked step, the application of Séguin's principles to normal children, stamps her a genius, if by this we are to understand a person who entirely intuitively recognizes a new truth. But I do know that her method is the product of intense and persistent work and that it is more in unison with the demands of physiological psychology than any other existing method. Free self-development of the child constitutes the device of the Montessori method. Nothing can be brought out from a child which is not within it, but qualities which it possesses may be allowed to wither or may be crushed; so also, without being forced, the same qualities may be developed, or, rather, may be allowed to develop themselves to their greatest possible activity. Whether the one or the other takes place, is entirely a question of method. In these times of steadily augmenting demands upon the activities of every person, that method is the best which will increase the individual's capabilities for action and adapt them to our ever-changing requirements, without in any way overstraining the child. Herein lies the differentiating test. This surcharging is often not so much dependent upon the fact that children are obliged to learn too much as it is upon the fact that the fulfillment of the task allotted has been made unnecessarily difficult through incorrect mehtods of training and instruction. The superiority of Dr. Montessori's method is due above all to the fact that she, in accordance with physiological psychological laws, adapts the principle of free self-development to the single stages of the child's progress and to its powers of comprehension, and in this way facilitates its acquisition of knowledge.

According to Wundt, the mental development of the child follows two principles—that of progression and that of evolution. Progression finds its expression in the fact that the development of the child advances in a certain well defined sequence, for which a preceding grade is always the necessary prelude to the following one, the acquisition of new capabilities therefore being possible only upon a basis of already existing ones. Evolution, on the

other hand, refers to the fact that certain capabilities are already present at the time of birth, and, one function creating the path for another, develop themselves from primitive to more and more complicated ones. The training and care of the child are, therefore, to be considered rational when they adapt themselves, in accordance with the single stages of development, to the traits and emotions with which nature has endowed the child and which serve for the maintenance of life. In such training and care two errors are to be avoided. Natural development should not be forestalled by demanding performances of the child which correspond to a higher plane, one which it has not yet attained. But neither must the demands remain behind or at that plane of natural development which the child has already outgrown in its natural advance to the next higher one. Over-activity is as harmful as under-activity. True pedagogic success is possible only when the cultural material with which we are dealing corresponds to natural progression and evolution.

The gratification of quiet meditative investigation certainly did not lead investigators to busy themselves with child psychology. All our knowledge in this field is due to the necessity for having an exact pedagogical basis. Those errors and failures which have hampered the old pedagogic system, found their explanation only when the strict correspondence to natural laws and rules, the development of the child's mental life, and the development of its bodily functions, had been recognized. Séguin and Guggenbühl had already recognized this truth in part. Froebel followed with his recognition of the great significance of the play impulse for mental development, and he in his system of education, made full use of this knowledge as a means for self-exercise, self-control, and self-instruction. Step by step the advance was kept up, until finally, through Wundt, physiological psychology attained its present development. But even this extraordinary progress remained incomplete, so long as the gauge was wanting with which to differentiate precisely between health and disease. Information of greatest value regarding the mental life of adults, as well as of children, could be gained only when physiological psychology through associating itself with pathological psychology had become true psycho-pathology. In the Montessori method the principles of both pedagogic as well as those of pathologic psychology of childhood are brought into use.

The premise for all mental development is furnished by the attention. Attention varies in degree. Under normal conditions the inability to concentrate the thoughts upon a certain object may be due to fatigue. But it is also possible that the lack of attention is caused by the inability to exclude other ideas which do not pertain to the matter in hand, or in an inability to connect associatively those concepts which are being acquired with those which are already present. Where the thoughts can be concentrated through learning, however, the acquisition of knowledge shows an interesting psychologic orderliness. We see how the attention is, automatically turned, so to speak, toward notions which impress us intensively, how those certain brain functions whose employment was at first possible only with great effort, little by little are transformed into automatic acts, and how the ideas upon which the automatic actions are based, step back from the threshold of consciousness which they originally occupied to a lower plane of consciousness, in order to make room for new impressions.

Wundt calls consciousness an inner seeing. But as we know, all sight impressions do not take place with the same clearness and distinctness, the variations depending upon whether they reach only the periphery of the visual field, or its center. The closer they approach the fixation point, the clearer are the perceptions, and the more they are removed from this point the more indistinct do they become.

It is precisely so in the various contents of our consciousness. Only a minimal number of the contents are brought to or reach a clear perception—figuratively speaking—in the fixation point of consciousness, while the majority remains obscured.

The entrance of a concept into the visual field of consciousness is designated by Wundt as perception, the entrance into the fixation point as apperception. This latter, by means of the attention, announces itself as an inner happening. The state of attention, inseparably connected with apperception, is called active when the process of apperception is associated with the feeling of self-performance. It is called passive, on the other hand, when a psychic happening, so to say, forces itself upon us and thus produces in us the feeling of submission.

Assuming the organ of special sense, the sensory nerves and the sensory centers to be intact, not only perception, but also apperception should, under normal conditions result. Nevertheless in many children the contents of consciousness do not rise to clearness and distinctness. Such children, for instance, do not fixate any object, even when it enters the visual field with the utmost distinctness. They are, so to say, lacking in apperceptional capacity. The contents of consciousness remain perceptionally isolated and therefore cannot be brought into those manifold relationships which form the basis of every activity of the mind. Under these circumstances no experience, not even of the most primitive kind, takes place, and even the constant recollection of an idea does not leave behind it a clear memory picture. It is for this reason that such children although their sensory apparatus may be normal, must be placed on a par psychically with those who, through defects of their sensory apparatus, are rendered incapable of receiving sensory impressions.

Whether the power of apperception is present may be determined best in accordance with Wundt's law of correspondence of apperception and fixation. This law shows that the visual lines of the normal organ of sight, by means of a surely acting central mechanism, become focused upon that object toward which our attention is directed. If no object, even when its rays fall upon the point of clearest vision, on the retina of the eye, is capable of exciting attention, then that determining impulse to fixation, which arises from the endeavor to obtain a clear and precise picture of the object is wanting, and no apperceptional power can exist. Consequently, also, all those mental processes which we designate as power of recollection, formation of concepts, and judgment become impossible. Upon the basis of this law of Wundt, it is possible to test the cultural capacity of feebleminded children, and we are able to differentiate three degrees of feeblemindedness:

First, the light grades, in which the capability is present of spontaneously directing the attention to various objects of the outer world, and still such active apperception fails to give the necessary clearness and distinctness to the resultant ideas.

Second, medium grades, in which the passive attention may be aroused, yet no spontaneous development of active apperception takes place.

Third, severe grades, in which even passive attention is wanting and, in which, therefore no culture is possible. Idiots whose powers of attention may be passively aroused, in whom intense sensory excitations produce distinct reactions, may be considered capable of being educated in so far as it may be possible to transform passive attention into active attention. The method of doing this consists in inducing the child to make a selection between various objects. Thus a new factor is aroused in the mind of the child, which may be designated as psychic spontaneity or self-activity. Not until this period of mental development has been reached is the feebleminded child capable of voluntary actions.

It seems to me the Montessori method is specially adapted to effect the transformation of passive attention into active attention, and it does this by means of the principle of self-development, as employed particularly in the development of sensory activity. Another method for the recognition of mental endowment is perimetry or the measurement of the visual field. This test depends upon the fact that every mental excitation produces a certain amount of brain fatigue which finds its expression in a restriction of the visual field. Inasmuch as the intenseness of mental application required to solve one and the same problem, varies in children of varied capabilities, fatigue of the brain with its resultant restriction of the visual field will occur more slowly in some cases, more rapidly in others.

By far the most reliable method for the evaluation of a child's intelligence is that series of tests evolved by Binet and Simon. By means of these, it has been said by a recent writer, the psychologist, after forty minutes' examination, can obtain a more enlightening estimate of a child's intelligence than can be reached by most teachers in a year of contact in the school room.

These intelligence tests consist in asking the child a series of carefully chosen questions, which can be answered by normal children of average intelligence. The questions are graded in accordance with the intelligence at different ages of normal children. If the answer of the child which is being examined corresponds to the intelligence of a child of its own age, then it is designated as normal. If, on the other hand, the child can answer only those questions which correspond to the powers of comprehension and to the conceptual sphere of younger children, then, according to the difference in age between it and the class which normally is able to answer those questions, it is classified as retarded, imbecile or idiotic. For instance, a child twelve years of age, having only the conceptual powers of a normal child of nine, would have to be classed as imbecile. Of course neither will this or any other method test the child's intelligence with mathematical precision. My chief concern has been to show that only that pedagogy can count upon success which accurately adapts its plan of training and instruction to the stage of development which the child has reached and to the contingent power of comprehension which it possesses. This applies in normal as well as in pathological conditions. Knowledge of physiologic-psychologic laws as well as of the methods for testing the intelligence and educational capability constitutes the essential premise for all promising pedagogic work.

Séguin and Guggenbühl instinctively strove for this exact pedagogic basis, but were unable to attain it. Madame Montessori has been more fortunate, for she had at her command the entire modern equipment furnished by physiology, pathology, and experimental psychology.

Recognizing that all mental development is dependent on the acquirement of ideas, and these in turn are dependent on sensory impressions, the Montessori method lays most stress upon the greatest possible perfectedness of sensory activities. The shutting out of single sensory organs in order to bring the action of others more intensively into play, as for instance the binding of the eyes and the "seeing with the fingers," in which objects, without being seen, are recognized through their consistency and conformation, is eminently adapted to training the organs of sense.

Since the child's own experiences constitute the most important and most potent educational material, the ways and means through which mental spontaneity is aroused in the child by Dr. Montessori's method of self-discovery must be of no little worth. For, inasmuch as this method allows the child to be guided entirely by its natural impulses and instincts, it adapts itself to the various stages of development and to the powers of comprehension which go with them. The play impulse little by little becomes converted into a desire for knowledge. First such simple ideas as those of form, number, etc., are derived by the child from the objects which surround it; then, through comparing the objects which it perceives in relation to their similarity or differences of form, color, etc., it learns to choose, and thereby develops judgment.

In the same way the highest faculty of the mind, the will, becomes developed step by step, by means of progression. Will-training is frequently confounded with will-breaking; but just as obstinacy is not an evidence of strength of will but, as shown by the inability to govern one's self, is an evidence of weakness of will, so the breaking of a child's will cannot be considered good discipline. True discipline is based upon freedom of action. Only that child is free which, through a strong will, has itself in its own power. Repression, the employment of coercive measures, may be convenient for the attainment of discipline, but it is pernicious, inasmuch as it inhibits the spontaneous activity and initiative so important in the struggle for existence. Measures of coercion must be confined to protecting the child against its own perilous acts. The exemplary discipline obtained in the Casa dei Bambini, founded by Dr. Montessori or conducted upon the principles she advocates, prove that we can get along very well without repression, and that the control which the children exercise among themselves fully suffices so to allow the will to develop in freedom that the rights of others are in no way transgressed.

To me it is clear, from what I know of Dr. Montessori's work, that the general introduction of her method would be the equivalent of a complete reorganization of our school system. That an amalgamation of Froebel's and Montessori's ideas in the kindergarten would give desirable results I doubt. It seems to me the future development of the matter will take place in the following way: Compromises between the current principles of training and instruction and the Montessori method, so different in its construction and ideas, will lead nowhere. Only something integral and decisive can be effective. Schools and houses of childhood must be established in which the Montessori principles will rule alone. Only thus will we be able to see which is the superior system. And, more especially we will then see

whether the greater efficiency undoubtedly attained in the Casa dei Bambini also gives advantages for later life. Whether the school boards will decide upon radical reforms in the sense of the Montessori method will depend upon the outcome of such pedagogic competition.

But, even without further delay, the Montessori method gives the greatest promise of success when applied to the training of those mental inadequates and those psychopathic inferiors who stand upon the border between mental health and disease and who are unable to keep pace with normal children. I again lay stress upon the fact that such apparent inadequacy and inferiority, with the consequent incompetency, are frequently due, not as is so often believed to stupidity or obstinacy, but to the fact that the pedagogy which to-day is sovereign in our schools has been unable to find the key to the mental life of these children. Careful individualization is of special importance in their cases, and, as Montessori has shown, the more the pedagogic method is adapted to the child's individual endowment the greater will be the progress obtained. Such individualization, however, is possible only if the degree of intellectual and cultural capacity possessed by the child be first accurately established. It is for this reason that I have thought it necessary to enter upon the question of psychological methods of examination, methods which alone enable us to form an opinion of value in regard to what is health and what is disease. Where mental defects are marked, the principle of free self-development will have to be modified in accordance with the individual degree of intellectual and educational capacity and, not by any means least, in accordance with the proclivities of character and will.

All spontaneous manifestations are naturally different under pathological conditions from what they are in normal children. Whether the Montessori method is new and whether it accords in every direction with the demands of present day pedagogy are questions of far less importance for me than the recognition that it is to-day the method which best fulfills the requirements of psychology and psychopathology. This is proved by the increased efficiency which the employment of this method has produced in very young normal and defective children. I therefore see no reason why this method should not be adaptable to the varied requirements of all cultivated peoples. But just as little do I doubt that it will share the fate of all good ideas; some day it will be replaced by a method of even greater worth.

## PRIMARY SPLENOMEGALY OF THE GAUCHER TYPE;

### REPORT OF A SUCCESSFUL SPLENECTOMY.

By WILLIAM A. DOWNES, M.D.,

NEW YORK.

My object in reporting the following case of primary splenomegaly of the Gaucher type is twofold—first, to call attention briefly to the clinical manifestations of this rare but extremely interesting condition; second, to record the second successfully operated case in this country, which, with Erdmann's case, the first operative recovery in America (to be reported shortly), brings the total number of operated cases up to seven. Of this number, there have been five recoveries and two deaths. The history of my case is as follows:

F. M., female, twenty-eight years of age. Born in eastern Tennessee and lived most of her life in the South.

*Family History.*—Father and mother living and well. One brother died of "brain fever." One brother living and well. Two sisters living. They enjoy fair degree of health. Each quite nervous. No history of similar illness in any member of the family. No history of tuberculosis or cancer.

*Past History.*—At six years of age patient suffered from a continued fever. She does not remember any of the symptoms. She was confined to the bed for six weeks. Had measles, mumps, whooping-cough, and chickenpox in childhood. Thinks she had malaria fourteen years ago. Had fever and headache. Does not remember having had chills or sweats. Took quinine at that time. Has had several attacks of tonsillitis. Three and a half years ago had rheumatism. For years patient has been troubled during the winter and spring with cough. No history of night sweats or fever accompanying these attacks. No history of pleurisy or pneumonia. Patient has had attacks of urticaria about once a year. Last attack during the past summer. No symptoms of lues. Appetite has always been poor. "Relatives thought that patient starved herself." Bowels during recent years showed tendency toward diarrhea. She often had two stools per day. At times she had five or six stools in the twenty-four hours. Takes coffee moderately, tea occasionally; does not use alcoholic drinks. Has always noticed that small sores or scratches were very slow in healing.

*Present History.*—Dates from childhood. She was never strong like other children, but always weak and easily fatigued. At thirteen years of age she was so weak that she consulted several physicians. At that time a mass was observed in the left hypochondrium. "Physicians did not know whether this was the spleen or kidney." She was quite pale and was given iron and arsenic. External applications were applied over the (spleen) tumor. She got stronger for a while and felt better. This was only temporary, however. She again began to suffer from general weakness. The patient felt the mass in her abdomen and noticed from time to time that it was increasing in size. She consulted other physicians who told her that the mass was her spleen. For years patient suffered from dull headache. This has been in the occipital region and has extended to the back of her neck. It was always worse at night.

For the past ten years the patient has been troubled with insomnia. She has suffered much from dull aching pain in the small of the back. This has been almost constant, but has varied in severity. She always felt as if "her back had been in a strained position." She has had a sensation of weight or heaviness in the abdomen. At times she has had pain in the left hypochondrium. For years she has experienced shortness of breath on slight exertion. Her limbs have felt tired and have ached as though her "bones were sore."

*Examination.*—General appearance is that of a rather severe anemia. There is pigmentation of forehead, sides of nose and cheeks, also chin. The conjunctivæ present, in a measure, the wedge-shaped thickening referred to by Brill. Practically the entire left half of the abdomen is occupied by a smooth fairly movable tumor which is without doubt the spleen. It extends to within two inches of the umbilicus and well into the pelvis. The liver is pal-

pable below the margin of the ribs, but is not much enlarged. There is no free fluid in the abdomen. Superficial lymph-nodes not palpable. No pain or tenderness elicited by pressure over long bones. Pelvic examination negative, except for moderate retroversion. Weight 113½ pounds. Examination of blood for malaria negative. Widal negative. Wassermann negative. October 4 she had 3,840,000 red cells, 1,400 white cells; polymorphonuclears, 60 per cent.; mononuclears, 40 per cent.; hemoglobin, 49 per cent. Urine showed trace of albumin. An *x*-ray examination of the abdomen was negative. Was put on iron and arsenic; during next three weeks gained four pounds in weight and hemoglobin went up to 57 per cent. However, the leucopenia became more marked, the count showing as low as 900 white cells per c.mm. on October 28. Under forced feeding and increasing doses of iron and arsenic, the blood picture began to show improvement. While the count had not changed materially the hemoglobin went up to 65 per cent. Her general condition seemed better in every way.

*Operation* was offered at this time and gladly accepted by the patient, December 14, 1912. The spleen was removed through an eight-inch vertical incision through middle of rectus. It was free from adhesions except posteriorly and these were easily broken by the hand after the pedicle had been secured. There were a number of anomalous vessels of large size, four or five, each of which was secured separately. A small cigarette drain was introduced at the center of the wound, as there was some oozing from a small tear in the mesentery. Very little shock.

Postoperative recovery was uneventful, excepting that day after operation she had a hemorrhage in the right conjunctiva, also an ecchymotic area size of the palm over the right buttock. Was then given 20 c.c. horse serum hypodermatically. No other evidence of tendency to bleed. Drain was removed on seventh day. Temperature ranged from 100° to 101° for twenty-one days, gradually coming to normal, wound healing *per primam*. Four days after operation had 3,860,000 red cells; 16,000 white cells; 97 per cent. polymorphonuclears; hemoglobin, 76 per cent. Discharged January 24, forty-one days after operation.

At that time blood count was 4,800,000 red cells; 8,800 white cells; polymorphonuclears, 45 per cent.; large lymphocytes, 16 per cent.; small lymphocytes, 26 per cent.; transitional cells, 8 per cent.; eosinophiles, 3 per cent. Now weighs 116 pounds. General condition improving rapidly. Shortness of breath has disappeared. Barring some pain in back shortly after operation she has suffered no discomfort nor has she had pain in the long bones.

*Pathological Report.*—By Dr. Tytler, New York Hospital. Weight of spleen with extravasated blood 1,813 gms. Measures 35 x 13.5 x 6.5 cm. Organ is of oblong shape, square at the postero-superior end and coming to a point at the lower anterior end. The thickness is fairly uniform so that the organ forms a flat slab, slightly thicker at the upper end. On the posterior margin at the junction of the middle and upper thirds is one deep notch extending nearly across the diaphragmatic surface, and above this in the middle of this surface is another short notch.

The surface of the organ shows a uniformly smooth and transparent capsule, save for scattered, very fine, transparent, dewdrop-like points of less than one mm. diameter. The color is uniform reddish brown with a grayish tinge. The organ feels rather firmer and more leathery than normal, of about the consistence of a soft liver.

On section, the organ cuts readily. The cut surface is flat, firm, and leathery, and considerably less friable than a normal spleen. The color is a reddish gray which on closer examination is seen to be due to innumerable minute gray points separated by a small amount of dark red substance. Here and there are seen scattered circular, dark red spots of about one mm. diameter which are distinctly raised above the surface. Trabeculæ almost indistinguishable and there is no evident increase of connective tissue about the main vessels.

The most prominent feature of the histological picture is an extensive, uniform, diffuse endothelial hyperplasia. The endothelial cells resemble those seen in the so-called "large celled hyperplasia" of lymph sinus endothelium, and form a solid mass or sheet lying sometimes within the sinuses but mostly between them. The cells are large and roughly spherical having a relatively large amount of faintly acid staining, homogeneous cytoplasm and relatively small, oval, vesicular, or smooth staining nuclei. The cell borders are indefinite and in the more solid masses cannot be distinguished. Where the cells are within the sinuses they often lie loose with the blood cells between them.

The sinuses are compressed by these cell masses but are still patent. They contain red blood cells—occasionally nucleated, numerous cells of the type of large lymphocytes, and relatively numerous polymorphonuclear leucocytes, mostly neutrophile. The sinus endothelium is hypertrophic but is not seen to be actively proliferating.

The pulp cords are almost obliterated, being represented by narrow bands of lymphocytes which separate the groups of endothelial cells. The lymph follicles are few and small but otherwise appear natural. From their distribution and size they apparently represent the darker points seen in the gross examination. The trabeculæ are not appreciably thickened.

The histological picture corresponds with that of the condition described originally by Gaucher as "Epithéliome primitive" and later by Bovaird as "Primary Endothelioma."

From the history it will be seen that the patient's symptoms began in early childhood, and at the age of thirteen a tumor was discovered in the abdomen. Pigmentation of the forehead, cheeks, nose, and chin had been present for many years. The conjunctivæ presented the wedge shaped thickenings. The superficial lymph-nodes were not palpable. The liver could be felt about one inch below the ribs. She was not jaundiced. There was no free fluid in the abdomen. Barring a marked leucopenia and rather severe anemia, examination of the blood showed no changes. She had never suffered from epistaxis or hemorrhages from the mucous membranes, although she had noticed that her flesh bruised easily and that small scratches and sores were very slow in healing. Her general condition was very fair. She was able to go around in a limited way, and enjoy herself, but the fatigue and sense of weight in her abdomen caused distress and it was on account of these symptoms that she sought relief. This clinical picture, extending as it does over so many years, corresponds almost exactly to that associated with primary splenomegaly of the Gaucher type, and should have been sufficient to have suggested that diagnosis.

However, my attention had not been called to the

literature of this subject and I had failed to profit by the excellent work of Bovaird, Mandlebaum, and Brill. To the latter belongs the credit of establishing the clinical diagnosis of this type of splenic hypertrophy. Four cases occurred in one family in Brill's practice, two of which were proven by autopsy. The disease is distinctly of the family type, but also occurs in isolated cases. The case here reported belongs to the latter class, for examination of the brother and sisters fails to show enlargement of the spleen. Although Mandlebaum has shown that the lesions occur in the bone-marrow, lymph-nodes, and liver as well as the spleen, the tendency to malignancy is so slight it would seem that removal of the spleen, the original seat of the disease, is indicated in every case, barring, of course, those afflicted with complicating diseases of a severe nature. The cases from which the spleen has not been removed usually die of some intercurrent disease. In the case herewith reported, splenectomy has worked wonders even in this short time. The hemoglobin has gone steadily up, the shortness of breath has disappeared, fatigue has given way to a sense of well being, and in every way the patient has changed for the better. She considers herself cured.

I would refer those interested in the detailed pathology of this disease to F. S. Mandlebaum's recent article in *The Journal of Experimental Medicine*. Dr. Mandlebaum has very kindly furnished me with the statistics of all the cases of splenomegaly of the Gaucher type, proven by examination of the spleen or by autopsy, recorded in the literature up to the present time. My case brings the total to twelve. The list of cases is appended in the order of their appearance.

Case I.—Gaucher, 1882. Female, aged 32 years; spleen was enlarged for 25 years; pulmonary tuberculosis developed before death.

Case II.—Follier, 1895. Female, aged 6 years; abdomen became large when two years of age. At autopsy, bronchopneumonia and pleurisy; no tuberculosis.

Case III.—Picou and Ramond, 1896. Female, aged 32 years; abdominal affection noted at age of 28 years; following a trauma; operated for fibroid of uterus; large spleen found and removed. The patient recovered.

Case IV.—Bovaird, 1900. Female, aged 16 years; abdomen began to enlarge at age of 3 years. Splenectomy; patient died three hours later.

Case V.—Brill, Mandlebaum, and Libman, 1904. Male, aged 34 years; spleen began to enlarge at age of 19; died of hemorrhagic pericarditis. First male case reported; lesion in bone marrow described for first time.

Case VI.—Schlagenhaufer, 1907. Female, aged 41 years; abdomen began to enlarge at age of 5 years; at autopsy, generalized miliary tuberculosis found.

Case VII.—Von Herczel, 1907. Female, aged 37 years; abdominal enlargement noticed at age of 33; spleen removed; patient recovered.

Case VIII.—Marchand, 1907. Female, aged 44 years; splenic enlargement noted at age of 35; death due to asthenia.

Case IX.—Brill, Mandlebaum, and Libman, 1909. Female, aged 37 years; enlarged spleen noted at age of 21; death due to fracture of the skull.

Case X.—De Jong and Van Heukelom, 1910. Female, aged 12½ years; splenic enlargement noted for five years; spleen removed; patient recovered.

Case XI.—Mandlebaum, 1912. Male, aged 4½ years; enlarged spleen noted for one year; splenectomy; patient died the following day. Youngest recorded case, and second male case reported.

Case XII.—Downes, 1913. Female, aged 28; enlarged spleen for fifteen years; spleen removed; recovery.

Note.—Since the manuscript of this article was submitted for publication Wilson has reported three cases of primary splenomegaly (Gaucher), from the Mayo Clinic. Two of these cases (Nos. G-8869 and A-9315) have previously been recorded by W. J. Mayo (*Journal A. M. A.*, January 1, 1910). The pathological report in both was given as chronic hyperplasia. For this reason the cases could not be included with those previously recorded in the literature as primary splenomegaly of the Gaucher type.

## A METHOD OF CLASSIFICATION, DIAGNOSIS AND THERAPY OF KIDNEY DISORDERS, BASED ON FUNCTIONAL TESTING.

By HERBERT EDWIN BARIGHT, M. D.

NEW YORK.

It was not so very long ago that nephritis was considered a disease entity which, according to duration and severity, showed varying symptoms and varying pathological lesions. That was the view held by Richard Bright who first in 1836 pointed out the connection between anatomical changes in the kidneys and the occurrence of albuminuria and dropsy. The same view was held during the period of brilliant pathological research which followed: the period that included the names of Henle, Virchow, Ludwig, Traube, Cohnheim, and Klebs and that gave rise to the anatomical classification of kidney lesions now in use. In 1879, however, Weigert demonstrated that these lesions represent, not the successive changes of a single disease process, but different processes or disease entities; that is, different types of nephritis.

Parallel with the pathological development of the subject, proceeded the study of the functions of the kidney. At first it was considered that there was but one function; that in the glomerulus a simple filtrate was pressed out which represented in all essential features a very diluted urine, the constituents of which had the same degree of concentration as that which they had in the blood serum. In the course of its passage through the tubule, this filtrate, this diluted urine, was condensed by reabsorption of a portion of its water. According to this theory, the composition and degree of concentration of the urine depended chiefly on blood-pressure and the varying composition of the blood, without implying any secretory or glandular activity on the part of the kidney structure. This was the view held by Ludwig and his school. In opposition to this theory, Bowman and Heidenhain taught that the function of the normal kidney depends upon a specific secretory capacity of the renal cell.

It was finally realized that neither theory alone would explain all the facts. As so often occurs in medicine, here also it was shown that in many respects both schools were right. At the present time, therefore, we can speak of a combination of the two theories which at first seemed so contradictory.

The modern view of the normal functioning of the kidney may be expressed somewhat as follows: First, chiefly in the glomerulus, by a simple process

of filtration, dependent, therefore, upon blood-pressure and upon the chemical composition of the blood, the urinary water and crystalloids are separated from the blood serum. Second, in its further course, chiefly in the tubule, this primary urine is concentrated by water reabsorption and at the same time enriched by the addition of certain organic and inorganic constituents. Some of these constituents are separated from the blood by osmotic action, while in other cases there is a true synthetic—therefore glandular—action. Functionally, then, we must distinguish at least three kidney processes; simple filtration, osmosis and synthesis or secretion. It has been said that chiefly in the glomerulus one function is performed, and chiefly in the tubule, the others. In the studied and necessary reserve of that statement lies, perhaps, a clue to the tangle in which we find ourselves involved when we attempt to match clinical and functional with pathological findings. They will not match; at least not with the precision and the certainty which is the aim of scientific medicine.

Because of this lack of correspondence between clinical and pathological findings, there has been for many years a tendency to substitute for the pathological a clinical classification or nomenclature of kidney disorders. It was Friedrich Müller who first, I believe, proposed that we diagnose at the bedside dropsical or nondropsical nephritis, instead of chronic parenchymatous, or chronic interstitial nephritis, or large white kidney, etc. But this was found to be an inexact basis of distinction for the reason that other symptoms were found—uremia for instance—sometimes in one form; sometimes in the other. Widal, later, proposed a third group which he called the "azotemic," or uremic type. But still there was overlapping and inconsistency, and this classification never made much headway toward general adoption.

So long as observation was limited to the human being, it was impossible to find exact analogues, either functional or anatomical, for the conditions dealt with at the bedside. New light came with the method of experimental pathology when it was found that different drugs, administered to healthy animals, cause injury to different parts of the kidney structure. By the administration of cantharides, for instance, a certain type of disorder could be produced and then studied and tested with laboratory precision. By the administration of corrosive sublimate and certain other drugs, other types of disorder could be produced. But these types were constant. The same drug produced always a disorder that had the same functional and pathological characteristics.

The next problem was the correlation of these experimentally produced types of nephritis with known clinical types. This correlation has finally, but not as yet completely, been accomplished by the method of functional testing. The method is, briefly, as follows: Certain comparatively harmless substances are administered to normal animals and the time required for complete elimination is noted. These same substances are then administered to nephritic animals of various types and the elimination time is again noted. The same substances are then administered to human subjects, both normal and nephritic—or suspected nephritic—and the elimination time determined. It has been found by Schlayer and his pupils in Europe and by Pearce and others in this country, that lactose elimination, for example, is delayed in the human being in those conditions which correspond, both symptomatically and pathologically, with experimental nephritis of the cantharides type, but not in other types. Similarly, potassium iodide and sodium chloride are delayed in clinical conditions which correspond with experimental nephritis of the sublimate type, but not in other types. These data are given in more detail in the accompanying schema.* Urea, employed as a test substance, is delayed only in conditions where there is a tendency to uremia—a tendency which is often found associated with the sublimate type, but which is also found, on rare occasions, as a pure type. The uremic type lacks, as yet, its experimental analogue and we do not know its histopathology. We know it only in its clinical manifestations. Clinically the type is fairly well defined. With the accompanying schema before us, let us now consider, from the standpoint of functional testing, the clinical characteristics of the several types of kidney disorders:

A SCHEMA FOR CLASSIFICATION, DIAGNOSIS AND THERAPY OF KIDNEY DISORDERS, BASED ON FUNCTIONAL TESTING

| Experimental Types | Cantharides | Corrosive Sublimate | | |
|---|---|---|---|---|
| Clinical Types | Vascular | Tubular | Uremic | Mixed |
| Percentage of All Cases | 40 to 50 | 5 | 5 | 50 to 40 |
| **Functional Tests:** | | | | Variable combinations |
| Excretion Time, Normal, Hrs. | Hrs. | Hrs. | Hrs. | |
| 2g. Lactose..... 4 | 8 to 12 | 4 | 4 | |
| 0.5g. Potassium iodide.....40 | 40 | 80 to 100 | 40 | |
| 10g. Sod. chloride.24 | 24 | 72 | 24 | |
| 10g. Urea.....24 | 24 | 24 | Retained | |
| **Clinical Signs:** | | | | Variable combinations |
| Heart..... | Hypertrophied | No change for years | Nor., or slight hypert. | |
| Blood vessels..... | Tendency to hemorrhage Tendency to spasm | Pallor of skin | | |
| Blood pressure..... | 180 to 250 mm.Hg. | Nor., or slight inc. | Normal | |
| Water excretion..... | Increased or normal | Retained | Normal, or inc. | |
| Specific gravity..... | Diminished or normal | Diminished | Normal, or diminished | |
| Salt excretion..... | Normal | Diminished | Normal | |
| Anasarca..... | 0 | + + + | 0 | |
| Uremia..... | 0 | 0 | + + + | |
| Albuminuric retinitis. | 0 | 0 | Constant | |
| Non-protein N. in blood serum..... | Normal | Normal | Increased | |
| Ambard's ratio..... | Normal | Normal | Increased | |
| Repugnance for meat | 0 | 0 | + + + | |
| Albuminuria..... | Variable; possibly 0 | + + + | + | |
| Formed elements in sediment..... | Variable; possibly 0 | + + + | + | |
| **Treatment:** | Reduce fluids and salt. Liberal diet, except with hemorrhage. No full baths | Reduce fluids No salt. Mixed diet. Hot baths useful | Fluids freely. In acute, no protein; in chronic, reduce protein to physiological requirements. No sweating | The dominant type |

1. *Nephritis with Delayed Lactose Excretion.*—This type is found pure—that is with normal iodide and normal urea excretion—according to Eppinger in 40 to 50 per cent. of all cases of nephritis. It is characterized, pathologically, by an endarteritis, not only of the glomerular vessels of the kidney, but also of the entire vascular system of the body. Because of this universal involvement and because, also, these lesions lead in time to sclerotic changes in the intima, with the inevitable accompaniment of high blood-pressure and hypertrophied left ventricle, this type of nephritis has been called vascular nephritis. The term serves the important purpose

*Adapted and enlarged from a schema given in lectures by Eppinger at the von Noorden Clinic, Vienna, 1912.

of reminding us that always, in this type of disorder, we are dealing, not with a local, but with a general condition. After febrile diseases, after tonsilitis, and in toxemic conditions, without the occurrence of other clinical signs and without the presence of demonstrable pathological lesion, incipient injury of the vascular mechanism can frequently be detected by the lactose test. Similarly, in conditions characterized by vascular crises, as in lead intoxication, angina pectoris, angina abdominis, intermittent claudication, transient aphasia and hemicrania, pareses, etc., where no other sign of renal involvement exists, positive results of this test will be obtained. The lactose test is a method in the interest of early detection, exact diagnosis and—as those clinicians who are employing it believe—a more rational therapy of this prevalent type of renal disorder. Schlazer first called attention to the fact that in the passive congestion of cardiac decompensation, lactose excretion is delayed. With restoration of cardiac integrity, the normal functioning of the kidney is resumed. Under the same conditions, functional deficiency of the liver is manifested by the occurrence of urobilinuria. But neither in the kidney nor in the liver—in transient passive congestion—can structural change be demonstrated.

Aside from lactose retention these patients have usually a sense of well-being and come to the physician, not for renal, but for cardiac troubles. They are often people whose physical work comes hard; who suffer from sudden attacks of angina pectoris, hemicrania, dizziness, great thirst and, with that, increased or normal output of urine. In more severe cases there may occur hemiplegia, due to vascular spasm and not to be confused with apoplexy: sometimes hemianopsia, edema of the lungs, sleeplessness, orthopnea, intermittent claudication and numbness of the hands and feet. These patients are subject also to hemorrhages in the kidney, hemorrhages in the retina, the brain, the stomach, in fact, in almost all organs, due to overdistended, sclerotic vessels. They never have true albuminuric retinitis, which is of toxic origin, but vision may be impaired by retinal hemorrhages and resulting scars caused by high blood-pressure and sclerosis. It must be borne in mind that as a rule high blood-pressure and the resulting cardiac hypertrophy are the dominating symptoms in this type of nephritis.

According to the anatomical nomenclature now in use the symptom picture we have drawn is that of the small white kidney. The brain symptoms—hemicrania, hemianopsia, transient pareses, etc.—have been considered uremic and have usually, I believe, been treated by withdrawal of meat and the administration of large amounts of milk. The disadvantages of this therapy are two: First, insufficient proteid supply, causing deterioration of the heart muscle and other working tissues; second, overdistension of the blood-vessels with fluid and unnecessary strain on the heart. With this mistaken therapy, heart troubles are apt to increase: edema, which may have been absent, developes from heart failure, or apoplexy prematurely closes the chapter. The mistake in therapy referred to has arisen from a misconception of the nature of the symptoms. They are not uremic but vascular. In pure vascular nephritis and in those cases which are of the mixed vascular and tubular type, probably 60 or 70 per cent. altogether, the nitrogenous elements are perfectly excreted—as may be determined by the urea test—and there is no reason for entire withdrawal of meat from the dietary. The symptoms mentioned, hemicrania, hemianopsia, transient pareses, etc., are due to vascular spasm. They are temporarily relieved by vasodilators, which would not be the case if they were uremic in origin. They are to be treated by limiting fluids and at the same time, in order to diminish thirst, by limiting salt.

In the medicinal treatment of chronic vascular nephritis, diuretin is the most important agent we have, not because it is a diuretic, but because it relieves the multiform subjective symptoms due to hypertension and arteriosclerosis. Diuretin dilates spasmodically contracted vessels everywhere. Albert Müller believes that this power extends to the *Vasa vasorum* and that for this reason its use in small doses over a long period by improving the nutrition of the vascular walls retards or checks the progress of arteriosclerosis.

Among the complications of vascular nephritis, hyperglycemia should be always in mind. The normal sugar value of the blood is 0.07 per cent. In vascular nephritis it may increase to 0.20 or even to 0.40 per cent. It is a malignant condition with a tendency to carbuncle, cataract, persistent, nagging neuritis and all the troubles of diabetes. No sugar appears in the urine, but it is to be treated along the general lines of diabetes.

2. *Nephritis with Delayed Iodide and Chloride Excretion.*—By far the most common and serious complication of vascular nephritis is that form of nephritis which is experimentally produced by corrosive sublimate and which appears clinically as a result of exposure or as a sequel of infectious fevers, like diphtheria, scarlet fever, pneumonia, etc. It is characterized pathologically by inflammatory changes in the tubular epithelium and has, therefore, been called tubular nephritis. When it is recalled that the efferent vessel of the glomerulus constitutes in its course the only source of blood supply to the convoluted tubule, and when it is recalled that in vascular nephritis this efferent vessel is diseased and narrowed by fibroid overgrowth and contraction of the intima, it will be readily understood that in vascular nephritis of long standing an imperfectly nourished and diseased tubulus is to be expected. The clinical characteristics of tubular nephritis so developed differ in no respect from those of the pure type which will now be described.

Tubular nephritis is seen in pure type in only 5 to 7 per cent. of all cases. Lactose and urea excretion are normal, while KI and NaCl excretion are delayed. In the clinical picture, edema and oliguria are in the foreground; the urine shows the presence of albumin and the sediment is rich in formed elements. In the chronic form lipoids and scanty blood corpuscles may appear, but may be entirely absent. The sodium chloride output is reduced and the specific gravity is low. The fluids of the edema contain large quantities of sodium chloride. Dropsy of the cavities is rare or very late and is more typical of the uremic form. Even in cases of long duration, increase of blood-pressure and cardiac hypertrophy never become very prominent—this in contradistinction to the vascular type.

In the purely tubular form the outcome into uremia is not observed. Death is rather the result of the dropsies or possibly of pulmonary edema. Since the therapy of tubular nephritis hinges largely upon the interpretation that is put upon the edema, this symptom must now be more closely analyzed. The average normal amount of blood in the human body is 5,000 c.c. If we represent this as a 0.7 per cent., that is, as a physiological salt solution, it corre-

sponds to a total of 35 grams NaCl. Thirty-five grams is the normal NaCl content of the blood. If now, to a patient with tubular nephritis who is already at the limit of his salt excreting capacity, 21 grams of NaCl in addition to the usual daily consumption be given in the food, this 21 grams of salt will be retained and will bring about a NaCl concentration of the blood above the physiological limit, which is 0.7 per cent. To restore the normal concentration, sufficient water must be retained in order to make of this 21 grams a 0.7 per cent. solution; that is, 3,000 c.c. If now we assume that in order to prevent undue salt concentration in the blood, this 3,000 c.c. of fluid is retained, we face a new difficulty. We have now to deal with an hydremia, a condition in which osmotic relations with the surrounding tissues are so changed that the excess of fluid, with its salt in solution, passes through the vessel walls and into the interspaces of the surrounding connective tissues, causing edema—a condition which is, therefore, primarily induced by the salt retention. If now we assume that salt be entirely withheld from the food and if we assume that the kidneys are able to excrete and do excrete, for example, 7 grams of salt per day, a reversal of the above process takes place. With removal of 7 grams of salt from the blood each day, none being added in the food, 7 grams of salt with a corresponding amount of fluid will pass from the tissues into the blood, and in three days, in the example we have chosen, the entire edematous accumulation will have been removed. In practice it is, of course, only in the gravest conditions that salt need be entirely withheld from the diet. By exclusion of milk, by using only meat that has been chopped and washed, butter and bread made without salt, and by adding no salt to the food, either in the cooking or at the table, the amount ingested can, in ordinary conditions, be kept within bounds; that is, within the excretory capacity of the kidneys. The best guide is the weight of the body which should be taken daily. In the beginning as much as 10 to 15 pounds of fluid may accumulate before any change in the appearance of the patient is noticeable by the eye. This so-called pre-edematous stage should be watched for with the scales.

Medicinally, diuretics, including diuretin, are contraindicated, because all of these drugs are irritants; they cause hyperemia and still further injure the tubular structure. Fischer's alkaline therapy—a therapy based on the presence of acids in the tissues of frog's legs which he had rendered edematous by constricting the circulation—has not been widely accepted:

First, because these alkalies are salts and all salts tend to increase rather than decrease the edema; second, because the edema which Fischer induced in frog's legs, with its attendant acidity, is believed to bear no direct relationship to the edema of tubular nephritis. As has been stated, the edema of nephritis is an edema of the loose connective tissues; it is an anasarca, and it never *directly* involves the protoplasmic tissues. Fischer's edema, if I correctly read his reports, involved not the connective but the protoplasmic tissues. Indirectly, however, in the most severe grades of renal edema the circulation of the limb may be so interfered with by the increased tension that a true edema of the protoplasmic tissues may be induced. In this condition salt-free diet gives no relief until the circulation is restored by relieving the tension. This is best accomplished by scarification or with Curschmann's needles. The edema of cardiac decompensation—a not infrequent complication of vascular nephritis—is to be distinguished from the edema of tubular nephritis. The former appears in the dependent parts and is accompanied by cyanosis, dyspnea, cold extremities, ascites, hydropericardium, etc. The edema of tubular nephritis, on the contrary, is a true anasarca; it does not appear in the dependent parts, but in the loose connective tissues, especially in the eyelids, in the fundament, in the scrotum and in the penis, in the dorsum pedis and under the tendo Achilles; breathing is quiet; there is no cyanosis; the hands are warm and pale. Only in the end stages are the serous membranes affected.

An actual case will, perhaps, best illustrate these points: Patient, a man of 55, with tortuous sclerotic vessels and blood-pressure of 208. Heart and aorta enlarged; apex outside the nipple line; second aortic tone loud and sharp; louder also at the apex than the first tone. No visible edema. On admission, however, three weeks ago, there was marked edema and a falling blood-pressure of 160; complexion dusky, and breathing difficult; urine 600 c.c. per day. That is, there was beginning secondary heart failure. To test whether the edema was in any degree due to tubular involvement, 10 grams of sodium chloride were administered in addition to the amount taken in the food. The patient was at that time excreting 6 grams per day. During the next twenty-four hours there was excreted 16 grams, showing unimpaired NaCl excretion; showing also therefore that the edema was due solely to circulatory trouble. The indicated therapy in such condition is, first, to restore the integrity of the heart action and thus reduce the edema. This was accomplished by the administration of digitalis and diuretin and by sharp reduction of fluids. In the course of treatment the water output reached 3,900 c.c. per day and blood-pressure gradually rose to its normal for this condition, which was, as stated, 208. He is now receiving and excreting daily 1,500 c.c. of fluid with body weight constant at its normal figure.

In the edema of tubular nephritis, digitalis, and diuretin are contraindicated. It should also be added, parenthetically, with reference to the sodium chloride test employed in the above case, that in the presence of actual tubular involvement this test is apt to provoke an acute edema. In doubtful cases therefore the iodide test is to be preferred.

3. *Nephritis with Urea Retention.*—Clinically this type of nephritis is rarely seen in pure form. It is a toxemia, due to the presence of nonprotein or "residual" nitrogenous products in the blood which should be excreted in the urine. Normally and in uremic-free forms of nephritis not more than 50 mg. of this kind of nitrogen is found in 100 c.c. of the blood serum. In uremics, on the other hand, the nonprotein content increases to 100, 200, or even 300 mg. The writer has seen no report of the working of Ambard's ratio[1] in pure uremic nephritis, but believes it would show increase. In these estimations then we have objective and positive tests for the presence of the uremic tendency. In the uremic form of nephritis it is very difficult to establish nitrogenous equilibrium in the individual. If one adds more albumin to the food the plus in contrast to the normal individual is not eliminated within the next twenty-four hours but requires several days—provided the kidneys succeed at all in eliminating it. Not infrequently such an increase in albumin is followed by the development of uremic symptoms,

which are: headache, feeling of fatigue, repugnance for meat, nausea, and vomiting. The vomitus frequently smells of ammonia. Further, diarrhea may develop; possibly spasmodic conditions which may go over into apathy and coma. Because of the repugnance for meat and all nitrogen-containing foods, these patients early suffer from deterioration of the muscles. This fact explains the misrelation between the deficient musculature and the well-developed panniculus adiposus usually observed. Along with these symptoms we find albuminuric retinitis. Let it be repeated that true albuminuric retinitis—due to toxemia— is not to be confused with the retinal hemorrhages of vascular nephritis, which are due to high blood-pressure and sclerosis. In the last stages hemorrhagic pericarditis or pleuritis may set in; the stool may show an alkaline reaction; the post-mortem shows intestinal ulcers. Many of the symptoms mentioned are protective measures on the part of the organism. With the retention of waste products, the attempt is made to eliminate by other channels; hence the urinous breath, the vomiting, and the diarrhea. Uremic ulcers are found in the intestines and lungs in no other form.

In the acute forms of uremic nephritis it is better to give no food at all, not even milk or soups, for these patients vomit everything, and the vomiting does harm which is not offset by the small amount of nourishment absorbed. The best plan is to give only water containing grape sugar and fruit juices. This "hunger cure" must not be continued longer than five days; but this period is usually sufficient to relieve the most acute uremia. If large amounts of urine are passed water should be given intravenously or subcutaneously, not with NaCl but with 4 per cent. levulose, ½ to 1 litre at a time. In very severe cases venesection is advisable. Complete withdrawal of albumin from the diet is to be risked only in the most acute cases. In chronic forms the minimum albumin requirement—1 gram daily per kilo of body weight—should be maintained, otherwise degeneration of the heart and other working tissues results from consumption of their own nitrogen. Milk may be administered in small quantities at frequent intervals, also fats and all kinds of carbohydrates and acid drinks.

Sweating baths have been so indiscriminately employed in all forms of nephritis, that it may be well to group here the indications and contraindications for this form of treatment. With sclerotic arteries and high blood-pressure, the dilatation or contraction of all blood-vessels of the body is attended with danger to the brain; hence, in vascular nephritis, full baths, both hot and cold, are to be avoided. The best plan in this condition is to employ only the sponge bath, and for only half of the body at a time; first, the upper half; then the lower half, avoiding extremes of heat and cold. In tubular nephritis, the sweating bath, properly controlled, is useful, for with a single treatment, 800 c.c. of fluid and 4-5 grams of salt may be removed from the body. In uremic nephritis, this form of treatment has not the same value; for, contrary to general opinion, very little urea is eliminated with the perspiration. In acute forms, sweating is distinctly contraindicated, for with the removal of so much water a concentration of waste in the blood occurs, and by this sudden concentration a true uremic attack may be precipitated.

4. *Mixed Types.*—Thus far we have referred only to pure types. As a matter of fact, with the exception of vascular nephritis, pure types are rarely seen. The percentages in the schema are those given by Eppinger.[2] Acute, beginning nephritis, is usually a mixture of the three types, with milk-sugar retention, strong KI and urea retention, some increase in blood pressure and perhaps hematuria, characteristic of acute glomerular irritation; oliguria and edema, due to tubular injury, and uremic troubles due to accumulation of nitrogenous wastes in the blood—not necessarily urea. This mixed, acute nephritis may entirely heal; or it may resolve into a chronic vascular, chronic tubular or chronic uremic type. The acute nephritis caused by exposure usually becomes predominantly tubular or uremic; the infectious forms more often resolve into the chronic vascular type. In treating mixed types, while taking into consideration the precautions imposed by each element, the general principles of treatment should be determined by the dominant type.

*Technique of Functional Testing.* (1) Lactose Test: First, exclude glucosuria by testing with Fehling's, Nylander's or Benedict's reagent. With strict antiseptic precautions, inject intravenously, 2 grams lactose in 20 c.c. of water. The solution employed should previously have been sterilized by heating at 75 to 80 C. for one hour on each of four successive days. At the expiration of four hours, empty patient's bladder and discard urine. Then collect urine every hour or every half hour and test for the presence of sugar. If sugar be found after four hours, there is suspicion of vascular impairment; if found after six hours, the indication is positive. (2) Iodide Test: This test is not to be employed in cases showing signs of hyperthyroidism. At 5 P.M. administer *per os* ½ gram KI. In health this entire amount should be passed within 40 hours; that is by 9 A.M. of the third day. Delay beyond 40 hours is suggestive of tubular impairment; beyond 60 hours, positive. Any iodine test may be employed. The following is suggested: Prepare starch solution by heating, but not boiling, for 2 to 4 minutes, 10 grains ordinary laundry starch in 10 c.c. of water. Add a few drops of this solution to 10 c.c. of urine. Add also a few drops of 10 per cent. sulphuric acid. Then underlay with concentrated nitric acid. A purple or blue ring at the level of contact indicates the presence of iodine. (3) Sodium Chloride Test: If tubular involvement be suspected, this test should be employed only with caution. First, the water and salt intake must be made uniform preceding and during the test and the urinary output of both determined. Administer *per os*, 10 grams NaCl with 1 liter of water in excess of the amount usually taken. Collect all urine passed as long as excess of salt appears. In normal conditions, 1 liter of water and 10 grams of salt in excess of the usual amount should be entirely eliminated in 24 hours. For quantitative estimation of NaCl, the following reagents are required: (a) Standard Silver Nitrate Solution: 29.06 grams are dissolved in distilled water and made up to one liter. Each c.c. is equivalent to 0.01 gram of sodium chloride. (b) Indicator: 100 grams crystalline ferric ammonium sulphate dissolved in 100 c.c. of 25 per cent. nitric acid. (c) Standard ammonium sulphocyanate solution. Dissolve about 13 grams in 800 c.c. of water. Titrate this solution against the standard silver nitrate solution and estimate how much water should be added to the remainder of the sulphocyanate solution to make it exactly equiv-

alent to the standard silver solution. The procedure is as follows:[3] Five c.c. of urine are pipetted into a small porcelain evaporating dish and diluted with about 20 c.c. of distilled water. The chlorides are now precipitated with exactly 10 c.c. of the standard silver nitrate solution and about 2 c.c. of the indicator added. Standard ammonium sulphocyanate solution is then run in from a burette until the first trace of yellow shows throughout the mixture. By subtracting the number of cubic centimeters of sulphocyanate thus employed from ten and multiplying by 0.01, the number of grams of sodium chloride in five c.c. of urine is obtained. From this the total chloride output for the twenty-four hours may be computed. (4) Urea Test: First, with a uniform nitrogenous intake, determine the urea, or better, the total nitrogen output. Administer 10 grams urea *per os*. This amount should normally be excreted in 24 hours. For clinical purposes, the hypobromite method of estimating urea will serve; but for more exact results, the Kjeldahl method of estimating total nitrogen should be employed. For the technique of these procedures, the reader is referred to Wood's "Chemical and Microscopical Diagnosis," third edition, 1911, page 476.

*Conclusion.*—By reference to the accompanying "Schema," it will be observed that as diagnostic signs, albumin and casts lose the preeminence which they have hitherto enjoyed. Both signs may be present in every type of renal disorder; hence, in an effort to distinguish between types, they possess no diagnostic value. In place of these, a series of signs is presented which possess true diagnostic meaning and value. Circulatory troubles are peculiar to, and therefore diagnostic of, vascular nephritis; anasarca and diminished capacity for salt excretion are peculiar to the tubular type; repugnance for meat, albuminuric retinitis and increase of non-protein nitrogen in the blood are peculiar to the uremic type. Aside from these purely clinical signs, we have the functional tests, each of which has its definite and unequivocal diagnostic significance.

The phenolsulphonephthalein test has not been here discussed for the reason that its value seems to pertain to prognosis rather than to diagnosis. It is useful for determining the extent or severity of a renal lesion, but not its type.

As is implied in the title of this paper, only a *method* has been here presented; not a completed nor perfected system for classifying, diagnosing, or treating kidney disorders. Further experimentation and observation will doubtless make many changes in our "Schema;" matters that are now obscure will be cleared up; new tests and new clinical signs will be discovered; some of these will doubtless be thrown out; new interpretations will be placed upon those that remain; a better therapy will be developed. The data here given and the deductions therefrom may all be swept away, and yet, if the method—like the scaffolding of some as yet unseen structure—but serve the scaffolding's purpose—enough. The method is neither easy nor quick. The functional tests, especially, are not well adapted for use in private practice. They must be simplified. Meanwhile, the method is, as has been said, a method in the interest of *earlier detection, more exact diagnosis,* and a *more rational, efficient therapy*. That fact must justify its presentation at such length.

## BARLOW'S DISEASE IN AN INFANT FED ON PASTEURIZED COW'S MILK.*

By CHARLES A. PFENDER, M.D.,

WASHINGTON, D. C.

ASSOCIATE IN CLINIC FOR DISEASES OF CHILDREN, CENTRAL DISPENSARY AND EMERGENCY HOSPITAL; ASSISTANT IN CHARGE TUBERCULOSIS CLINIC.

The first account of infantile scurvy appeared about 53 years ago in an article by Moeller, who vaguely described this disease in 1859 under the name of acute rickets. The report aroused very little interest among medical men, and no further progress was made in the study of this pathological entity until 1883, when Barlow gave a comprehensive account of the pathological and clinical characteristics of this disease and directed the attention of observers to the importance of proper dietetic therapy.

Infantile scurvy has been spoken of under the various designations of acute rickets (Moeller), hemorrhagic rachitis (Fuerst), Barlow's disease, Moeller-Barlow disease, hemorrhagic periostitis (Smith), and infantile scurvy. The penchant for attaching the name of the discoverer to all worthy results of individual effort has led us to immortalize the name of Barlow in this connection.

Barlow's disease is a constitutional disease occurring in infants, and results from a more or less prolonged error in diet, and it is my purpose to confine my discussion chiefly to the part played by human breast milk and pasteurized, boiled, or raw cow's milk in the production of this disease.

No doubt we are all agreed that mother's milk is the ideal food for babies, but, unfortunately, it is not always available. The reasons for this are numerous and some of them only too obvious. It is an accepted fact that 10,000 individuals control the entire wealth of our nation and in a large measure shape the destiny of the remaining 90,000,000 or more. It stands to reason that only a small proportion of our population, therefore, is so situated financially as to be removed from the worry and care incidental to the struggle for a livelihood. The vast majority is constantly engaged in a fierce battle for existence, and notwithstanding the announcements in the press that an era of unprecedented prosperity surrounds us on every hand, we, as physicians, daily and hourly come in contact with the most squalid conditions of habitation, reeking of poverty if not of filth, and in those cases where degradation and vice have not triumphed as the result of desperate straits we still find the deep furrows of worry and trouble upon the countenances of those who are endowed with inherent principles of decency and self-respect. It is written in the Scriptures that in the sweat of our brow shall we earn our daily bread, but we might add incidentally that they do not specify that we should sweat blood, as so many do. The 10,000 just mentioned rarely ever sweat, unless it be when threatened by legal processes for some rascality committed at the ex-

*Read at the 49th regular meeting of the George Washington Medical Society, Washington, D. C., December 21, 1912.

pense of the more or less helpless 90,000,000. On the other hand, the Good Book tells us also that the poor will be with us always, and therefore we need to be prepared in a measure to deal with those phases of human life that constantly confront us.

Some of you may ask what has that to do with the subject in hand? I'll tell you. Nature has ordained that mammal females should suckle their young and has made ample provision therefor. The human species is no exception. From the earliest records of human existence we have evidence of the mother nursing her child until it had attained an age when it could forage on its own behalf. The women of uncivilized nations of to-day without exception feed their babies from their own breasts. A large proportion—a proportion, however, which is constantly lessening—of the women of civilized life suckle their offspring. There are others, however, who do not suckle their young, and that is due to several causes, by no means the least of which is the havoc brought about in the human economy by the struggle for an honorable existence. Unfavorable and unsanitary surroundings, poverty in any form, worry, strife, unhappiness, no matter from what cause, all exert an inhibitory effect on the galactogenous action of the female breast, with the result that some mothers lack the galactiferous stimulus entirely, never having any milk in their breasts, others perhaps manifesting only a transitory activity in the milk glands, while others again, although presenting actively functionating glands, may formulate a product that is far from wholesome and which is detrimental to the infant. Under such conditions —and the number is greater than you think—other means of feeding must be devised if the infant is to survive.

Now, as regards infantile scurvy, I admit that I have never observed this particular disease in breast-fed infants, nevertheless it is an established fact that this disease may occur in children fed exclusively on breast milk. We note from the literature that in 379 American cases of infantile scurvy 12 cases occurred in breast-fed babies. The literature records cases by Ashby, Ausset, Cima, Crandall, Freund, Fruitnight, Hochsinger, Koeppen, Love, Mather, Northrup, Petrone, Scott, Soltmann, Southgate, and Weiss. The majority of these cases are said to be open to criticism. The case reported by G. Freund in *Deutsches Archiv für klin. Medizin*, v. 86, p. 129, and the case described by Hochsinger before the Vienna Medical Society and published in *Semaine médicale*, Paris, 1909, p. 312, will, however, bear the most critical analysis, and there is not the slightest doubt that these cases were true infantile scurvy occurring in babies that had always been fed on mother's milk only. We are forced to concede the possibility of Barlow's disease occurring in breast-fed infants just as rickets has been known to develop in these children, but after all it is of rare occurrence. When scurvy appears in breast-fed infants it is no doubt due to the absence of the so-called antiscorbutic principle in the mother's milk.

Clean and pure raw cow's milk, modified to the requirements of the infant, is the best artificial food product we have at our command. I know of no case where scurvy developed while properly modified raw cow's milk was fed to babies. Unfortunately it is not always to be obtained. One can probably procure raw cow's milk wherever he may be within the confines of our nation, but no difficulty has been encountered in demonstrating the absence of the two first mentioned properties. Here again the mode of living, civilization so to speak, is largely accountable for the contamination we so justly dread, and it is due to the possibility of transmitting diseases to children by the pathogenic microorganisms contained in cow's milk that scientists were induced to recommend the heating of milk before feeding it to infants. It has developed, however, that scurvy is such a common occurrence in children fed on boiled or sterilized cow's milk that boiled milk is now almost universally condemned as a food for babies. . Laboratory experiments and practical observations have fully demonstrated that if we subject cow's milk to an intense heat we deprive it of some essential properties of wholesomeness, and it is assumed that this process forms a product which exerts a toxic effect on the bony and vascular system, or certain combinations essential for the normal process of metabolism are destroyed, with the result that specific nutritional disturbances arise in the bones and vessels of the infant. Whenever boiled or sterilized milk is used for any length of time scurvy is almost certain to manifest itself sooner or later.

Pasteurization, *i. e.* heating cow's milk to a temperature of 155° F. (68° C.) for 20 to 30 minutes, has been found more satisfactory in actual practice. Pasteurization apparently does not produce any chemical or physical changes in the milk, and yet it effectively destroys all pathogenic microbes contained therein. As it is, unfortunately, a rather difficult task to obtain clean germ-free milk at times, especially during the summer months, and more so in the temperate and tropical regions, pasteurization is recommended. It has been observed, however, that it is not advisable to continue with pasteurized milk indefinitely, and Kerley earnestly advocates that pasteurized milk be used only during the four hottest summer months and that raw milk be given during the remaining eight months of the year, so that the child may escape any harmful results that frequently follow the long continued administration of heated cow's milk.

Thus far it has not been my good fortune to observe a case of scurvy in an infant nursed by the mother's breast or fed on properly modified raw cow's milk, and I observed this summer the first case of infantile scurvy, due to pasteurized milk, that occurred in my practice. The disease has been so rarely reported in infants fed on pasteurized milk that I failed to consider carefully such a possibility when I was called to see the child; and the absence of some of the cardinal signs of scurvy when I examined my patient in the beginning of the trouble led me to pursue my investigations in other directions. In fact my perceptions were lulled by the belief that scurvy would not be likely to develop in a child fed on pasteurized milk. In a review of the literature on the subject some time later I found it almost universally accepted that scurvy practically never occurs in children fed on cow's milk that has been pasteurized.

Holt states that in his entire career he has observed only three cases of Barlow's disease which were due to pasteurized milk, while Neumann, in his wide experience, observed only one case in which pasteurized milk caused scurvy, and in this case the child had been on pasteurized milk for some time and had recently been given milk which had been heated for 10 minutes at a temperature of 98° C. It is not impossible that other cases have been observed, but I failed to find any reports thereof

in the literature. The purpose of this paper is to report the case which I referred to, but before doing so I would solicit your indulgent attention in a brief discussion of recent animal experiments in which raw, boiled or sterilized, and pasteurized milk was employed. There has been very little experimental work done in this line and the data is exceedingly interesting and instructive.

Peiper and Eichloff fed one series of dogs for 5 and 6 months with sterilized (boiled) milk and another series with raw cow's milk. In the dogs fed with the sterilized milk pathological changes were found in the bones and bone-marrow and in the periosteum. Those fed on raw cow's milk, on the other hand, remained healthy. Esser fed young goats with sterilized (boiled) milk and later demonstrated in these animals similar bone changes as occur in infants with scurvy.

Froelich, of Christiania, carried out a series of experiments with guinea-pigs which are quite interesting. He found that when guinea-pigs were fed with raw cow's milk only they soon died, and autopsy revealed a markedly brittle condition of the bones, but none of the other changes common to scurvy. He then fed barley and sterilized (boiled) milk to one series and barley and raw milk to another. The guinea-pigs which were fed on barley and raw milk grew fat and were killed after 118 to 138 days. Autopsy showed no pathological changes, and microscopic examination of 67 ribs and all femora and tibiæ failed to disclose any sign of scurvy, nor did the bones appear brittle. In the series in which the milk was heated for 10 minutes at 100° C. and 60 minutes at 112° C. respectively the animals lived from 34 to 97 days, but they did not thrive. At autopsy all animals showed loosened teeth, typical scorbutic hemorrhages, marked brittleness of the bones and fractures were noted in the majority of the animals. Microscopic examination revealed typical scorbutic bone-marrow changes.

Holst of Christiania has shown that when guinea-pigs are fed on barley alone scurvy invariably occurs, associated with a brittle condition of the bones. Froelich showed that raw milk alone caused brittleness of bones in every case, but no scorbutic symptoms. When both barley and raw milk are fed, however, the animals remain perfectly well and autopsy fails to reveal any pathological changes, while boiled milk and barley produced typical scurvy associated with brittle bone conditions. Heating cow's milk for 10 minutes at 100° C. robs it of its antiscorbutic property against guinea-pig scurvy. Again, when the milk was pasteurized (heated for 30 minutes at 70° C.) the antiscorbutic properties proved effective in all those animals which had ingested large quantities of milk, while in those which had consumed small quantities of milk various pathological changes and scurvy could be demonstrated.

Although these results of experiments on herbivora cannot be indiscriminately applied to the human species they nevertheless point the way to further observations along similar lines. Admitting for the sake of argument that this so-called "antiscorbutic" substance is diminished in pasteurized milk, and assuming that the animal conditions are analogous to those in man, we would expect to observe like results in babies fed on pasteurized milk, and this is probably what happened in my case. Just why scurvy does not occur in more cases fed on pasteurized cow's milk still remains to be solved.

Case.—Walter T., white, born September 19, 1911; fourth child of intelligent parents in moderate circumstances. I saw this child for the first time on October 12, 1911; he was then 3 weeks old. The mother stated that labor had been very tedious and difficult, that she had nursed the baby for 10 days and then had to resort to cow's milk and a patent food, as the milk in her breasts had quickly disappeared. The boy weighed 10 pounds at birth; when 3 weeks old he weighed only 9 pounds. Physical examination revealed nothing unusual or abnormal with the exception of an inguinal hernia which was reduced. It did not recur. As the stools were watery and green two drams of oleum ricini was ordered and the child placed on 6 per cent. lactose solution for 24 hours, followed by a milk and cream formula of 1 per cent. fat, 0.5 per cent. protein, 7 per cent. sugar; seven feedings, 4 ounces every 3 hours. This child did well and the formula was gradually increased to 2 per cent. fat, 1 per cent. protein, 6.5 per cent. sugar; seven feedings, 5 ounces every 3 hours. Weight, November 24, 10 pounds. The formula was increased at this time and directions left for adding more fat if progress justified it. I did not see the child again until February 13, 1912. Improvement had not been so rapid as was desirable, and, since the milk employed was of a low fat percentage, I advised a change to pasteurized milk containing 4.5 per cent. of fat. The baby was then 5 months old. Top milk mixtures were prepared and the child improved rapidly in nutrition and gained in weight. When the boy was 6 months old barley gruel was substituted for the boiled water in the feeding formula (2.3 per cent. fat, 2 per cent. protein, 6 per cent. sugar). On April 30 and again on May 16 acute double otitis media necessitated paracentesis of both tympana, which was followed by discharge of serosanguinolent fluid and immediate cessation of symptoms. The child ceased to cry, dropped asleep within an hour—after having cried constantly for 12 hours—and the temperature fell from 104° F. to 100° F. within the next three hours. Hexamethylentetramine, 3 grains every four hours, was ordered. Soon afterwards the food was increased to 3 per cent. fat, 2 per cent. protein, 6 per cent. sugar. This was followed by progressive improvement and increase in weight until July 17. Then the child appeared to be in great pain, cried shrilly, appeared tender to the touch about the hips and insisted on assuming a relaxed attitude with the thighs as mentioned. There was no fever, no disdromal symptoms, and the attack occurred during the middle of the day. Manipulation of the lower extremities caused much pain. Physical examination failed to disclose anything further than the tenderness and relaxed, flaccid condition of the things as mentioned. There was no fever, no discoloration of the gums; reflexes were present and active; there was no local redness, edema, swelling, or paralysis. The peculiar relaxed pseudoparalytic position of the lower extremities was suggestive of poliomyelitis, which I excluded, however, by ascertaining the absence of impairment or change in the reflexes and the absence of the reaction of degeneration when tested with the faradic and galvanic currents. Rheumatism was excluded by absence of fever and local signs, although the mother stated that she had sustained repeated attacks during her period of gestation with the child in question. Syphilis was also excluded on account of negative family history, absence of skin lesions, and lack of any other manifestations of this disease. The child got better in a day or two, ceased to be fretful, was

content to lie on his back or sit in the cart, but made no effort to use the lower limbs. When I visited the little fellow again during the course of a fortnight the mother stated that just prior to the eruption of the incisors the gums had appeared bruised, probably caused by falling against a roll of the go-cart. Examination at this time showed the child to be well and contented and the gums were not swollen and were normal in color. In August the food was changed to full milk two parts and barley gruel one part with sufficient sugar added to make 5.5 per cent. Orange juice was ordered on general principles, but the mother failed to give it because the child did not like it. On September 17 the pain and tenderness about the hips became acute again. Suspecting possible hip-joint involvement, I made two radiographs of the pelvis, but these showed no signs of osteitis of spine or joints. The first upper molars were about to erupt and at that point the gums appeared darker and more swollen than is usually the case. Although still unsuspecting the true nature of the illness I again ordered orange juice for its laxative effect and beef broth and meat juice in addition to the milk and barley mixture, and the child improved again. The tenderness and pain gradually subsided again. On September 30 I was called to see another child in this same family and took advantage of the opportunity of inspecting the baby again. He appeared somewhat improved, only the molars were causing some trouble. The gums over the molars were very red and congested, but the remaining portion of the gums was normal in appearance. I suggested a consultation in the hope of arriving at a diagnosis, and found that this would be acceptable. On October 2 Dr. H. H. Donnally saw the child with me. Examination showed the gums about the upper incisors swollen and inflamed, while the gums over the erupting molars were bluish-black in color and much swollen. Apparently no physical defect anywhere. Exquisite tenderness of legs and thighs, but no swelling or enlargements. The child cried on manipulation of limbs, but less than at previous times, a fact noted and commented upon by the mother at the time. In view of the swollen and discolored gums, the tenderness of the thighs and hips and absence of any definite lesions, Dr. Donnally established the diagnosis of infantile scurvy, and in this I heartily concurred after noting the condition of the gums. I procured a specimen of urine which showed a specific gravity of 1,015, was pale amber in color, and contained no albumin or sugar. Centrifugation gave a red deposit which on microscopic examination was found to be composed of erythrocytes, which findings further confirmed the diagnosis. I incised the gums over the erupting molars on the following day and the child appeared considerably relieved thereby.

The pasteurized milk was stopped and raw cow's milk ordered from the same dairy. Oatmeal gruel was substituted for the barley on account of the tendency to constipation. The importance of the administration of orange juice was impressed upon the mother and the drinking of from one to two ounces daily was ordered. Meat juice and scraped meat was also added to the diet. October 6, child is improving; gums normal. October 9, general condition progressing well and molars have erupted. Child is beginning to play with his feet and kicks his legs energetically; he has no pain or tenderness on palpation or excessive manipulation. Makes no attempt to stand, crawl, or walk. October 28, child is much better and is beginning to have a rosy color of the face for the first time. He appears lively and happy and makes frequent efforts to stand. He sleeps well at night and acts in every way like a perfectly healthy child.

In summing up the symptoms we find that there was very slight anemia manifested by a moderate pallor of the skin of the face and conjunctivæ. Pain and a form of pseudoparalysis were present, but no enlargement of the bones. There was slight hemorrhagic swelling and softening of the gums. No hemorrhagic swelling of the eyelids and no exophthalmus. No extravasation of blood into the skin or mucous membranes. There was no hematuria, but erythrocytes were present in the urine. Fever was absent throughout. It is evident that a certain proportion of antiscorbutic properties still persisted and prevented the development of a severe typical case of scurvy.

304 Rhode Island Avenue, N. W.

## SOME OF THE COMMON FORMS OF INSANITY.*

By EDWARD GILLESPIE, M.D.,

BINGHAMTON, N. Y.

SENIOR ASSISTANT PHYSICIAN, BINGHAMTON STATE HOSPITAL.

During the past five years 1,290 patients have been admitted to the Binghamton State Hospital, exclusive of transfers. Classifying these according to the official classification of the New York State Hospital Commission, 230 were diagnosed as senile psychoses, 163 were diagnosed as manic depressive, 136 were diagnosed as dementia præcox, 87 were diagnosed as alcoholic psychoses, 84 were diagnosed as general paretics, and 69 were diagnosed as involution psychoses; so that a total of 769 patients, or practically 60 per cent. of these admissions, fall under one of six psychoses. I will, therefore, give a brief definition of each of these six psychoses together with a word as to their etiology, symptomatology, and prognosis.

*Senile psychoses* are those occurring usually after 60 years of age, the characteristic symptoms being progressive mental deterioration. As to the etiology, the usual signs of senility are present; defective heredity is found in a large proportion of cases, and with these predisposing factors mental and physical overexertion with excesses of any kind are active causes of the psychosis. The symptoms commonly found are defective memory, especially for recent events. These people may be fairly clear as to events which occurred years ago, but new impressions are not retained. Their minds are no longer receptive to facts which take place from hour to hour or day to day. Their attention is also defective and they fail to understand the connection of things. They become childish, petulant, irritable, restless and discontented. They not infrequently mistake the identity of persons, mistaking strangers for persons whom they formerly knew well. They develop delusions, usually of a persecutory nature, are apt to be restless at night, wander away without proper clothing, play with fire, place lighted lamps on lighted stoves and in other dangerous places and thus become a menace to those with whom they live. The prognosis is bad, since the disease is due to advancing years.

*Manic depressive psychoses* comprise those forms of mental disorders which recur in definite forms

*Read before the Binghamton Academy of Medicine, November 19, 1912.

at intervals during the individual's life, and in which there is little tendency to deterioration. The first attack usually occurs before the age of 25. In this group are many of the cases which were formerly diagnosed as recurrent mania, recurrent melancholia, circular insanity, and alternating insanity. As to the etiology, defective heredity is found in a vast majority of cases. With this as a predisposing factor, gestation, alcoholic excesses, mental shocks, and acute diseases act as exciting causes. Three forms of this psychosis are generally recognized:

First, the manic form characterized by psychomotor excitement, flight of ideas, distractibility, pressure of activity, happy but unstable emotional condition, and unstable delusions. Second, the depressive form characterized by psychomotor retardation, dearth of ideas, absence of spontaneous activity, emotional depression, and stable depressive delusions and hallucinations. One readily perceives that the symptoms of the depressive form are exactly the opposite of those found in the maniacal form. The third is the mixed form which consists of a mixture of the symptoms found in the two preceding forms.

By "flight of ideas" is meant a rapid change of ideas expressed by the patient. He starts to express an idea but before he has completed the expression he begins a new one and before this is finished, still another, etc., etc. The goal idea is wanting; he is continually going off on a tangent—he never gets anywhere. For example: A patient had written some letters and when asked why he had written them, said: "To pass away the time; I have been doing a lot of things that are decidedly foolish, writing these letters; you see I have known Dr. H. here. I thought the work was divided up, surgical, medical, and, of course, the brain is a study by itself. Well, I don't know just how to say; well, I tried to get a college education without going to college; now speaking medically, what I mean that I—well a—well—a—I want to purchase some stuff and I don't know how much has been used and how much has not been used."

By "distractibility" is meant the more or less constant change of thoughts, actions, etc., due to passing external influences. For example, when the patient is talking the jingle of keys is heard and immediately he will begin to talk of locks, doors, jails, or something having reference to keys. If a bell is rung he will talk of church, school, dinner, or something with which a bell is intimately connected, etc. By "pressure of activity" is meant that the patient is more or less constantly "busy" doing this "this, that or the other thing" and accomplishing little or nothing. By "dearth of ideas" is meant an actual lack of ideas; they have few ideas, and those they have form slowly. Not that they lack the necessary mental ability, but that they have difficulty in elaborating external impressions. By "psychomotor retardation" is meant difficulty in putting into action various groups of muscles. For example, when the patient is told to "stand up" he has great difficulty in making up his mind to bring the necessary muscles into play and he rises slowly, inch by inch, not from weakness but because of the slowness of his mental processes and the great effort it requires to get the muscles in action.

The prognosis is good for an individual attack, but recurrences are frequent. The duration between the attacks is extremely variable; from a few hours to months and even years. Only a very small percentage (4 or 5 per cent.) of the cases do not recover from an individual attack, unless the case is one in which there have been many previous attacks. Of course, repeated and severe attacks must sooner or later leave the patient with some degree of dementia.

*Dementia præcox* is a psychosis that appears early in life, usually before the age of 25, and is characterized by a progressively chronic course with certain fundamental symptoms, of which progressive mental deterioration is the most prominent. From 14 to 20 per cent. of all admissions to all state hospitals have this psychosis. Etiology: Defective heredity is extremely common, being found in about 70 per cent. of the cases. Many individuals who develop this psychosis have shown mental peculiarities from youth; such as precociousness, seclusiveness, impulsive actions, and great susceptibility to alcohol. Many also present asymmetries, malformations, strabismus, etc. Acute diseases sometimes act as exciting causes. Many have been reared under improper mental hygiene and it is generally believed that much may be done with individuals who have a tendency toward this psychosis by improving the mental and moral as well as the physical conditions under which they develop. Symptoms: The individuals are usually self-absorbed, shy, silly, sullen, obstinate, careless; they are inactive, accomplish little or nothing, smile and laugh without apparent cause. The emotional attitude is changeable. They are usually dull and indifferent. They develop many delusions and hallucinations, especially of a sexual or absurd nature. In some cases the delusions are of a persecutory character and have a tendency toward systematization. Other common symptoms are stupor, catalepsy, impulsive outbursts of violence and even suicide; negativism, in which the patient does exactly the opposite to what one wishes him to do and what a normal person would do; mannerisms (certain peculiar actions which are frequently repeated, sometimes for hours at a time) and the frequent repetition of words, phrases or sentences. Memory and judgment become progressively impaired. The prognosis is bad. The vast majority, over 85 per cent., go on to deterioration.

*Alcoholic psychoses.* Those most commonly seen are the acute alcoholic hallucinatory type and delirium tremens. The acute hallucinatory type is characterized by the sudden appearance of coherent delusions of persecution and jealousy based upon hallucinations of hearing with retention of clear consciousness. The delirium tremens type is characterized by the sudden development of fantastic hallucinations of sight and hearing; indefinite and changeable delusions, mostly of fear, often of a religious nature, with clouding of consciousness. Etiology, a defective state of nutrition which usually exists for days; gastritis, with the imbibing of alcohol; shocks, injuries, and acute diseases, especially pneumonia. Symptoms: They are much the same in the two diseases. The onset is rapid, with insomnia, uneasiness, and hallucinations of all senses, especially of sight and of hearing. In the hallucinatory type, the hallucinations are not fantastic, but form the basis for coherent delusions, while consciousness is clear. In the delirium tremens type there is marked psychomotor excitement with marked clouding of consciousness. The prognosis is good for the individual attack.

*General paralysis* is characterized by progressive mental deterioration with symptoms of excitation

of the central nervous system, leading to absolute dementia and paralysis; and, pathologically, by a definite series of organic changes in the brain. Etiology: Probably due to a syphilitic infection, either inherited or, as happens in practically all cases, acquired. It is more commonly found in men than in women and usually begins in middle life. With the existence of the above predisposing cause, mental stresses, alcoholic excesses, and sexual excesses are the principal exciting causes. Symptoms: The disease occasionally begins with a rapid onset; a marked maniacal attack, convulsions, or apoplectiform seizures. Usually, however, the onset is slow and insidious, with a feeling of incapacity, neurasthenic symptoms (inability to perform mental labor, lack of power of sustained application), defects of memory in little things and failure to recollect recent events; there comes a change in disposition, the person who was formerly even-tempered but now becomes easily irritated; he becomes lacking in moral sense and careless in his personal appearance; he who was formerly particular about his necktie and the way his hair was combed and moustache curled now becomes more and more indifferent to these. His pupils are sluggish in the reaction to light or fail to react at all; the extended fingers show a fine tremor, as do the muscles of the face, especially about the mouth, and there is a tendency to slurring in speech, particularly for labials and dentals. Especial difficulty is experienced in saying certain test phrases: "Truly rural" (tooly looly). "Methodist Episcopal" (metodist epistobal), "electricity" (elescity), etc. The face gradually loses its expression, the tremors become more marked, the knee jerks are irregular, sometimes exaggerated, sometimes diminished or lost entirely; pupils become unequal and lose the reflex action to light, and the intellect shows marked weakening, which becomes very apparent in the lack of judgment the person displays when compared with his judgment when in his normal condition. This lack of judgment is seen not only in his moral conduct but also in business matters, in his entertaining poor business propositions, making rash investments, etc. Delusions of grandeur develop and seizures are common until finally the patient becomes soiled and wet, his muscles become so weak that he can no longer walk about with safety, he becomes bedridden, and trophic sores develop. As the muscular system becomes weakened, so does the osseous system, the bones become more brittle and fractures from insignificant causes are common. The prognosis is bad, no true case of general paralysis have ever been known to recover, although intermissions are sometimes seen. The ultimate outcome is death and the average duration is about three and one-half years after the beginning of the disorder.

*Involution melancholia.* A psychosis appearing during the involution period, characterized by depression, with fear; delusions of self-accusation and persecution, with moderate clouding of consciousness and disturbance of the train of thought. Etiology: It usually occurs between the ages of 40 and 60, is more common in women, and is preceded by worry and anxiety, lasting for prolonged periods, for months or a year or more. Heredity, mental shocks, acute and chronic illnesses, etc., are among the causes. Symptoms: The onset is gradual, extending over months. The person becomes sad, dejected, apprehensive. She searches her conscience for some explanation of her worry and fear, recalls some little sin committed in her youth, remembers stealing candy from a store or a penny from her mother's purse, etc. She develops delusions of self-accusation and unworthiness, and the delusion that she has committed the "unpardonable sin." She becomes restless and agitated, makes frequent threats, and attempts to commit suicide. Her train of thought is usually coherent and relevant. She is well oriented and has a good memory. The prognosis is fair. About half of the cases recover and a fair proportion of the other half show greater or less improvement.

The descriptions, etiology, and symptoms given above are about as brief as they could be and at the same time are sufficient to give a little insight into the psychoses mentioned. But I am aware that the physician in general practice has little time for "specializing," particularly when it comes to insanity, for his reading must of necessity be largely "general." Therefore I have given only the salient facts in the hope that, when so little is said, most of it will be interesting and easily digested.

## A NEW TREATMENT FOR ACUTE GONORRHEA.

By O. L. MULOT, M.D.,

BROOKLYN, N. Y.

At the present day, when among physicians, especially in the larger cities, there is an almost universal tendency to specialize, it seems indeed a bold thing for a general practitioner to dare to treat a condition or a disease that belongs to a special field; and it is still more bold to imagine that he has discovered something new in such a field. Yet that is what I, who have steadfastly refused to allow myself to be drawn from the broad and interesting field of general medicine, am about to do by reporting the results which I have obtained in the treatment of acute gnoorrhea, and for which I sincerely believe I can claim priority.

The progress that has been made in medicine and surgery during the last 25 years is wonderful; and while this progress has been made in many fields and is a just subject for our modest pride, we certainly cannot claim that any really great strides have been made in the treatment of acute gonorrhea. The treatment of this disease by vaccines or bacterines is reserved by the most experienced men for the chronic cases. There is another feature to this form of treatment that restricts its use, namely, the point of cost. The consensus of opinion seems to be in favor of the autogenous vaccines, and these are sufficiently costly to make the patient pause and try other means of cure before he agrees to this more costly treatment. In many cases this proves short-sighted economy; nevertheless, it is a condition which frequently confronts the physician. Otherwise than by use of vaccines in chronic gonorrhea, the treatment of this disease has undergone little change.

Not alone has the treatment of gonorrhea been unsatisfactory to the patient from the standpoint of time necessary for a cure, but the physician also has realized that this old treatment is far from entirely harmless, for the effect of the balsams upon the kidneys is the very reverse of good. We know that they produce an active congestion of these organs, and while we have been taught to view this as ephemeral, it must be a question whether, when this treatment is continued over a long period, this

is still true and that no permanent damage has been done to these vital organs. Furthermore, we must consider this effect of the balsams when administered to a patient whose kidneys already are the seat of some lesion. Under such conditions the result certainly would be bad, since the balsams surely aggravate the existing process, and such an aggravation could not logically be of an only ephemeral character. But even if there be no previously existing nephritic lesion is it reasonable to conclude that an active congestion of the kidneys, resulting from the therapeutic use of balsams in gonorrhea and which apparently disappears after the discontinuance of the drug, that this does not leave the kidneys in a state of weaker resistance for the future? I cannot pretend to authoritatively answer these questions, but to me they seem worth serious pondering; surely all will agree that personally each of us would prefer to go through life without having our kidneys subjected to a congestive condition induced by balsams.

Locally, too, there has been nothing distinctly new. It is true that new silver compounds have been devised, but still these have not yielded strikingly superior results.

The foregoing, then, may fairly be considered a résumé of the treatment of gonorrhea as generally practised to-day, and it is the one which until very recently I too, have followed.

During the past summer a patient suffering from gonorrhea presented himself to me for treatment. A mixture of balsams was ordered for him, and it did him the usual amount of good; at his next visit to me an injection of the sulphocarbolate of zinc was added to his treatment. On his third visit, which was about the tenth day of the disease, the idea of treating this disease locally with iodine suggested itself. I recalled the tolerance of the oral and the vaginal mucosa to tincture of iodine and the frequent good results which are obtained with it in gynecology. There was something fascinating in the idea, and I concluded then and there to find out how the urethral mucosa would act toward iodine, and I tried a dilution of Lugol's' solution. This first experiment certainly was painful to the patient, but the next morning there was a decided improvement in the discharge, enough so to warrant further search for some means by which this drug could be used in this condition. The next day I tried iodine in a blend of oils, and this was injected into the urethra with very little smarting and held there fully five minutes. The patient remarked that the smarting perceptibly lessened even during the time that the oil solution was in the urethra. This solution was given to him with instructions to use it three times a day. The next day he reported that the first injection had been without discomfort, but when he repeated it, it smarted violently. Nor is this strange when we recall the effect of iodine when applied at too short intervals; but he reported further that the discharge had almost disappeared. He was now ordered to make the iodine injection only once a day. Two days later he reported that the discharge had entirely disappeared and he stopped the injections, but in a few days the discharge reappeared. He was now directed to use the iodine once a day and the sulphocarbolate of zinc injection twice a day, and under this plan of treatment, within a week his discharge disappeared permanently.

My next case of gonorrhea came to me while I was still treating the foregoing. It was in a man without any previous venereal history. He received no internal medication of any kind, but was at once put on the oleaginous iodine injection. At first he did not prove apt at the art of urethral injection, and therefore there was not the prompt response to treatment that I had expected; but two days after he had mastered the art he very joyously informed me over the telephone that there was no longer anything the matter with him. From my experience with the other case I told him not to crow too soon and that I would see him at his office in a day or two. When I did see him he told me that the discharge had reappeared. I then ordered him to follow the same treatment that I had instituted in the latter part of the treatment of the previous case, and within a week's time had the satisfaction that he, too, reported himself definitely cured.

In the above two cases the iodine was used in 5 per cent. strength; one of the patients complained that it smarted rather severely. In the subsequent cases the iodine was combined with another oil-soluble antiseptic, which enabled me to use a weaker strength of iodine with practically the same effect, but with less discomfort to the patient. The result of this treatment in the other six cases was just a little better, owing to the knowledge that something more than just the iodine was necessary, such as the sulphocarbolate of zinc, to bring about a definite cure. I do not intend to claim that maybe something else than the sulphocarbolate of zinc might not act just as well, but that just happens to be the thing that I had used very much in the past in treating gonorrhea before I devised this iodine treatment. Nor is the strength of the sulphocarbolate of zinc solution a matter of indifference; it should not be stronger than to have a just fairly perceptible sting; if stronger than this it can do more harm than good, and I think this is true of the strength of the solution of another substance which we may fancy to substitute for the sulphocarbolate of zinc. In every one of the eight cases to which this treatment was applied the diagnosis was verified by the microscope.

I believe that this treatment is applicable also to streptococcus and staphylococcus infections of the urethra.

The best results of this treatment can be obtained if the doctor will himself make the iodine injections, leaving the other, such as the carbolate of zinc or some other substance for the patient to make for himself, because relatively few patients succeed well with these, particularly at first, and the sooner this treatment is instituted the better the result will be. I tried a solution of iodine in glycerin, but this even in the normal uninflamed urethra, smarted, and this smarting increased the longer the solution was left in place; the smarting was still evident during micturition hours later, and it was evidently very unsuitable.

Of course we cannot and must not expect the same results from this in chronic cases; usually during the third week the posterior urethra becomes involved. Then the disease is in a territory that is particularly favorable to its spread and to spread into regions in which it becomes strongly buttressed against attack by ordinary means of treatment. The seminal ducts, the prostate, seminal vesicles, etc., all these about the end of the third week become more or less involved and no injection into the urethra can reach them; but from these remarks it must not be concluded that this treatment would prove entirely valueless in chronic cases. In such cases

after an intelligent massage of the parts and these washed out by micturition, then an injection of iodine may reasonably be expected to do *some* good, but it would be indeed optimistic ignorance to expect such prompt results as I have reported for this treatment in acute cases. It is just in the chronic cases in which the microbe has become established in inaccessible places that the vaccines afford us a means of treatment and have yielded the most brilliant cures.

We must not allow ourselves to be misled into the belief that the treatment of chronic gonorrhea is the more important; while proportionately we see more chronic cases than we do acute ones, every chronic case of this disease had its acute period. Many chronic cases have been treated by reputable physicians; comparatively few cases become chronic from neglect or lack of treatment. Every physician has acute cases of this disease drag along three and four months in spite of his best efforts, simply because there has been no really effective treatment for the acute stage. With an effective treatment for the acute stages, there certainly should follow a diminution of chronic cases.

In submitting this report of my experience with iodine in the treatment of gonorrhea I fully realize that it covers only a very small number of cases, but the uniformity of the results and the fact that all the cases had the common factor of acuteness certainly offers some definite data for our consideration. If by the use of this drug we can at once attack the disease locally, save the kidneys from an acute congestion, ephemeral or not, as that may be, save the patient from the digestive disturbances which these balsamic mixtures so often cause, then it is important. Furthermore, if by this treatment we can obtain a cure of an acute gonorrhea in a week or ten days, thus avoiding the complications so common to the latter stages—gonorrheal arthritis, then the sequelae—prostatic disease in later life, then this treatment is indeed important and my early report justified.

424 Halsey Street.

## A CASE OF ACUTE SEPTICOPYEMIA.

By T. G. ORR, M.D.,

NEW YORK,

HOUSE PHYSICIAN, ST. MARY'S FREE HOSPITAL FOR CHILDREN.

The following case is reported from Dr. George M. Swift's service at St. Mary's Free Hospital for Children.

F. W., male, aged two years and ten months, was admitted to the hospital October 25, 1912. Family history negative except for the death of a ten-months-old baby brother three weeks ago with "convulsions." Cause of convulsions not known. The patient's general health has always been good. He has never had any of the acute diseases of childhood or other prolonged illness. For the past four weeks has had an infected finger on the right hand. The onset of the present illness was five days before admission. The first symptoms noted were fever, loss of appetite, and fretfulness. During the first night after onset the patient was extremely restless and slept very little. The following morning he had a convulsion. This was soon followed by a chill and a severe pain in the abdomen located in left upper quadrant. For the next four days before admission his condition gradually became worse. He had a slight cough, continued high fever, at times delirium and a persistent pain in the left upper abdomen.

Physical examination: The patient is well nourished and developed. Lies quietly in bed in a semi-stupor when undisturbed but is quite irritable when aroused. Face pale and drawn. General appearance not unlike the typhoid state. Tongue has heavy gray coating, mouth and lips dry, teeth covered with sordes. Temperature 102.8°, pulse 128, respirations 48. On the face and forehead are large irregular areas of erythema, the edges of which are in some places palpable. Like patches are distributed irregularly over the body and extremities. Ears, throat, and eyegrounds negative. No rigidity of neck. The lungs are clear throughout except a few fine crackling râles low in the left axilla just to the left of the heart apex. Point of maximum impulse of the heart is in left fifth interspace 5.5 cm. to left of midsternal line. Cardiac dullness extends from 6.5 cm. to left of midsternal line in fifth interspace to 2 cm. to right in fourth interspace. A short, soft systolic murmur is heard at the apex, not heard at base of heart or in left axilla. Heart regular. Pulse rapid but good volume and tension. The abdomen is distended and tympanitic. Liver palpable 1 cm. below costal margin, and not tender. Very marked tenderness and some muscular rigidity along left costal margin. Mass felt in left hypochondrium extending 4 cm. below the costal margin. Palpation of this mass causes acute pain. Dullness over mass continuous with splenic dullness. No notch felt. No movable dullness in abdomen. Tip of second finger of right hand infected. Infection extends beneath the nail, a portion of which is loose. A drop of pus expressed from beneath nail. Deep reflexes normal.

On October 26, the day after admission, there was slight rigidity of the neck muscles. Kernig's sign negative. A lumbar puncture was done and 25 c.c. of clear liquid were withdrawn under normal pressure. Examination and cultures from this liquid were negative. General condition unchanged. October 27. The erythema is still present but has varied much in past two days, sometimes being absent entirely. Today there appeared many small petechiæ on the flexor surfaces of the arms near the elbows, a few on the chest, neck, and legs, and many in the inguinal regions. Slight edema of feet and ankles. Dullness at apex of left lung posteriorly with voice and breath sounds bronchial. Heart regular. No change in heart sounds except that these are somewhat weaker. Tenderness in splenic region persists. Von Pirquet test negative. Temperature ranges between 103° and 105°. Patient has taken very little food since admission. Death occurred early in the morning of October 28 the fourth day after admission and the ninth day of the illness.

Laboratory findings: Urine negative. Leucocyte count on admission was 24,000 with 75 per cent. polymorphonuclears. These rose the day before death to 55,000 with 75 per cent. polymorphonuclears. Examination and cultures from spinal liquid negative. Blood culture grew the *Staphylococcus aureus* and a culture from the infected finger grew the same organism in pure culture.

In view of the above findings the following clinical diagnosis was made: Acute endocarditis with emboli to spleen and left lung forming infarcts. Source of infection probably infected finger.

Positive autopsy findings reported by Dr. W. C.

Clarke. Body of male child aged two years and ten months. Well nourished. Dressing on second finger of right hand. Thorax and abdomen opened. Lungs red and congested. At apex of left lung is a dark and solid area which on section shows an infarct about 2 cm. in length surrounded by marked consolidation. Heart muscle pale. Portions of mitral valve covered by exudate which is adherent. Spleen markedly enlarged, measuring 6 x 4 x 11 cm. One large and several small gray areas beneath capsule. Capsule in one place adherent to parietal peritoneum. On sections there are three very definite infarcts. An infarct at the lower pole measures 3 cm. in diameter. Also several small irregular areas of similar appearance. Both kidneys pale and mottled by small pale areas which on sections have the appearance of small infarcts. Brain and cord not examined.

Microscopical examination: Heart: Muscle markedly infiltrated with lymphocytes particularly in the perivascular areas. Scattered throughout the tissue are multiple abscesses. The blood vessels in many places are plugged by thrombi containing micrococci in pure culture. These colonies are usually limited to the vessels but in a number of areas they have broken through the vessel wall and infiltrated the surrounding tissue. This tissue shows a number of infarcts. The cells of the heart valves are edematous and the lymph sinuses contain many lymphocytes. Lung: Sections through consolidated area show pneumonia in stage of red hepatization surrounding a large infarct. Spleen: Very markedly infiltrated with lymphocytes with multiple abscesses. The sections practically show no evidence of normal tissue. The blood-vessels over extensive areas are thrombosed by colonies of micrococci which have in many places invaded the adjacent tissue. Some of the blood vessels are thrombosed by large blood clots with extensive extravasation of blood in the immediate vicinity. At one point in the section is a large infarct. Other smaller infarcts are scattered throughout the section. Kidney: The blood-vessels show many thrombi due chiefly to the growth of micrococci. The destruction of tissue is quite as marked as in the other organs. The epithelial lining of the tubules has been destroyed in many places.

The above case is reported because of its comparative infrequency, and because of its interest from a diagnostic standpoint.

## Medicolegal Notes.

**Consent to Operation—Modification of Rule by Use of Anesthesia.**—A surgeon undertook to operate free of charge upon a rupture in the plaintiff's left groin. When the patient was put under the anesthetic the three surgeons present discovered another more serious rupture in the patient's right groin. The surgeon operated upon this, intending to operate also upon the other, but was prevented from doing so by the patient's condition under the anesthetic. The patient apparently acquiesced in a completion of the operation on the following day, but later declined to go on with it and brought action against the surgeon for assault and battery. A verdict was given for substantial damages, which was set aside on appeal.

The surgical employment of anesthesia, it was said by the court, has modified the common-law rule that the consent of the patient must be given before the surgeon has a right to operate. This employment has not only eliminated the possibility of obtaining the patient's consent during the operation, but has also had other medical effects. It has rendered possible and of every day occurrence surgical operations of a character and magnitude not dreamed of at the time the common-law rule was in the making, and has also advanced the period that marks the commencement of a surgical operation from the time when the patient's body is actually invaded by the knife to the time when the anesthetic is administered, or at least when the patient has succumbed to its influence. It has also postponed to this same period of relaxation and unconsciousness the making of that complete and final diagnosis of the patient's condition that at common law was made at a time when he could be both informed and consulted. By these considerations the scope of modern surgical operations has been greatly enlarged, and the legal rule applicable thereto extended beyond the emergencies of actual surgery to other matters more or less vitally affecting the patient's welfare. To meet these changed conditions, the rule of law must, in the interest alike of the patient and the surgeon, be adapted to the changes that have been so wrought, chief among which is the unconscious state of the patient at a time when by the common-law rule his consent must be obtained. To meet this fundamental change in the condition of the patient, it is imperative that the law shall in his interest raise up someone to act for him—in a word, to represent him in those matters affecting his welfare concerning which he cannot act himself because of a condition that has become an essential part of the operation. If such a representative has been chosen by the patient himself, the rule has no application But if no one has been so appointed, the law will raise up such a representative. When a person has selected a surgeon to operate upon him, and has appointed no other person to represent him during the period of unconsciousness that constitutes a part of such operation, the law will by implication constitute such surgeon the representative of his patient, and will, within the scope to which such implication applies, cast upon him the responsibility of so acting in the interest of his patient that the latter shall receive the full benefit of that professional judgment to which he is legally entitled. Such implication affords no license to the surgeon to operate upon a patient against his will or by subterfuge, or to perform upon him any operation of a sort different from that to which he had consented. In the present case a ruling that the operation was of a different sort from that to which the patient had consented would be based upon too narrow a view. Whether the rupture occurs on the right side or on the left the intestine is the same, the muscular wall is the same, the operation is the same, and its dangers and the risks are the same.—Bennan v. Parsonnet, New Jersey Supreme Court, 84 Atl. 948.

**X-Ray Photograph—Liability of Master for Injuries Thereby.**—An action proceeding on somewhat unusual facts was brought by a telephone lineman against his employers. He received an injury while in the performance of his duties. A physician was called, who diagnosed the case as a displacement of the sacro-iliac joint, and used heroic treatment that was claimed to have resulted in forcing the joint into place. The plaintiff was making good progress toward recovery, when the defendant's general manager requested him to submit to an *x*-ray picture being taken. The plaintiff opposed this, expressing his fear of injurious consequences, assuring the defendant's manager he was all right, and offering to release the defendant from all claims for damages on account of the injury. His physician also opposed the taking of the *x*-ray picture, but the manager guaranteed that the taking of the picture would not injure the plaintiff, and threatened to discharge him if he refused to submit. After a good deal of hesitation and resistance, the plaintiff finally consented to have the picture taken, and the *x*-ray was applied over his abdomen by a doctor employed by the defendant. The plaintiff testified that the current was left turned on for more than seven minutes. He claimed to have received a severe burning of the tissues by the application of the *x*-ray, and, as a result, to be suffering from paralysis of the bowels.

The relation of physician and patient did not exist between the doctor who applied the *x*-rays and the plaintiff The rule of *respondent superior* therefore applied rather than the law relative to the liability of a physician or surgeon to his patient, or to the liability of a master who employs a physician to treat his servant. The instrumentality was under the defendant's exclusive control, and there was sufficient evidence that injury to the subject is not a necessary result of the taking of the *x*-ray picture, if proper instrumentalities and proper care are used. The court could not say that the plaintiff's injuries were not the result of the exposure. The facts were enough to make the case one of *res ipsa loquitur*, and to make the burden on the defendant show that there was no negligence. That the defendant did not do conclusively. Judgment for the plaintiff was there- The rule of *respondent superior* therefore applied rather fore affirmed.—Jones v. Tri-State Telephone & Telegraph Co., Minnesota Supreme Court, 136 N. W. 741.

## A VERY BAD MEDICAL BILL.

A BILL recently introduced into the New York State Legislature, entitled "An Act to Amend the Public Health Law Relative to Medical Licenses," gives power to the Regents to revoke the license of a practitioner of medicine, annul his registration, or suspend him from the practice of his profession for any length of time, if he is guilty of unprofessional conduct. In principle there can be no objection to a law providing for the revocation of the license to practise for good and sufficient reason. There is already a statute to this effect which is not perfect, but is much to be preferred to the proposed amendment. One great defect of the latter lies in its definition of unprofessional conduct, which is both obscure and absurd.

This definition reads as follows: " 'Unprofessional conduct' means and shall include the following acts or conduct by or on the part of a practitioner of medicine: (a) Advertising either in his own name or in the name of another person, firm, association, or corporation, in any newspaper, pamphlet, or other printed paper or document, or writing letters or causing them to be written, or employing capper, solicitor, or drummer to secure patients, wherein or whereby the medical practitioner holds himself or herself out to cure diseases or defects of the sexual organs, or to cure chronic or incurable diseases, or for being employed by any person, firm, association, or corporation so advertising or announcing." Out of this jumble of words we gather that it is entirely professional to advertise or employ drummers to announce that one can cure all diseases save chronic diseases, incurable diseases, and diseases of the sexual organs. One may advertise that he can cure a chancre of the lip, but must keep silent as to his ability to replace a retroverted uterus.

Obscure as is the meaning of this clause, it is clarity itself compared with the next section: "(b) Announcing professional service without compensation or the acceptance of fees in consideration of the assurance that an incurable disease may be permanently cured." This sentence is absolutely meaningless as it stands. If it is intended to forbid a practitioner from telling a poor patient that he will not charge him anything, it is absurd and outrageous; it would also make every dispensary and hospital physician guilty of unprofessional conduct. Perhaps it means something else.

The next three parts of this wonderful definition read: "(c) Wilfully betraying a professional secret. (d) Habitual drunkenness or addiction to drugs. (e) Dividing or promising to divide a fee with another physician, or accepting a divided fee, without the knowledge of the patient or the person paying such fee."

Finally, if the Regents want to deprive a practitioner of his means of livelihood and cannot find that he has been guilty of any of the acts specified above, they can fall back on the last part of this definition: "(f) Any other action not consonant with good morals, or anything done or said detrimental to the health or morals of others."

It is incredible that such a bill should pass the Legislature, yet it is reported to have passed one branch and to be in a fair way to pass the other, so that the only hope of escaping its dangers lies in the Governor's veto. If he does not do so it will not be because he is ignorant of the will of the profession, for a number of medical societies have already passed resolutions criticising and condemning the bill and have petitioned the Governor to veto it.

## HERESIES IN POPULAR MEDICAL EDUCATION.

THE grammar-school teacher who told her pupils that all evil thoughts originate in the cerebellum had no doubt misconstrued what she had read regarding the lower functions of the brain. "A little knowledge is a dangerous thing" finds its fit application in many of the popular views on the human body and its diseases. The avidity with which persons of more than average intelligence frequently patronize the newer cults in therapeutics, and distrust the sounder teachings of the medical profession, illustrates the prevailing ignorance of the fundamental facts of physiology—an ignorance for which the common schools must be held largely responsible. The effort that has been made within recent years to educate the people by means of lectures, health exhibits, and articles in the press, when properly carried out, has accomplished good results. But in many instances this effort has degenerated into a mere exposure of the naked facts of disease without conveying the important truths underlying these facts. The "tuberculosis exhibit," housed in a dingy store, sometimes suggests the chamber of horrors provided in the dime museum of anatomy of a generation ago. The public press has assiduously cultivated the sensational aspects of the prevention and cure of disease. The monthly magazines have practically exhausted this theme, and a flood of books on health topics bears witness at once to the demand of the public and the business acumen of their authors.

The danger of disseminating error by means of the well-turned phrase or glittering epigram is one of the most important evils of the latter-day popularization of medical knowledge. There is a growing tendency to preach hygienic heresies and to cast aside established beliefs in favor of bizarre theories. There is a host of false prophets who delight in casting ridicule upon some of the cherished cus-

toms and wholesome habits of the people. The influence of these so-called teachers is directly proportionate to their prominence in the public eye, to their ability to gain a hearing at the national medical congresses, to their enterprise in getting a liberal "write-up" in the daily newspapers, and to their command of an attractive and forceful literary style.

In the recently published volume on "Common Diseases," Woods Hutchinson* discourses in his usual vein upon such subjects as pills and powders, dyspepsia, heart disease, seasickness, deafness, insomnia, etc. The well-informed reader, with the gift of humor, will find this book a most entertaining one. But the average reader cannot always distinguish between scientific truth and rhetorical exaggeration, between serious exposition and humorous allusion. There are many facts in medical science which cannot be "popularized" without serious distortion and without creating false conceptions that may ultimately result in serious harm. One who is regarded by a large number of people as an authority, may thus be instrumental in wielding a dangerous influence.

There are statements in this book that should not go unchallenged. The utmost in therapeutic nihilism is perceived in the following, "No drug—save quinine, mercury, and No. 606 in special cases—will cure a disease; only rest, food, sunshine, and fresh air can work that miracle." The medical reader can take this announcement with the necessary reservation, but the layman who is accustomed to read or decipher the prescriptions of his medical attendant, will be apt to conclude on the basis of the above statement that he is usually humbugged by his doctor. Hutchinson knows only three specifics in the materia medica: quinine, mercury, and salvarsan. What of ipecac in amebic dysentery, of thymol in hookworm disease, of iron in chlorosis, of arsenic in chorea, and of thyroid extract in myxedema? These are ignored nor is any attention paid to the host of remedial agents which though not specifics, may nevertheless restore the disturbed equilibrium that in many instances marks the real difference between health and disease.

Another instance of the modern method of enlightening the public is seen in the following statement: "The most effective direct treatment now given in Bright's disease is in the form of prevention, by recognizing it in early stages and giving antitoxins, serums, or antiseptics which will either kill the germ which has caused and perhaps is still keeping up the inflammation, or neutralize its toxins and help the system to get rid of them."

## DISPENSARY AND HOME TREATMENT OF TUBERCULOSIS.

A SOMEWHAT remarkable change has come over the attitude of the medical profession with respect to the treatment of tuberculosis. But a few years ago, in fact, not longer than two years ago, members of the profession who had made a study of the disease seemed to be practically unanimous in favor of sanatorium treatment. Sanatoriums sprung up everywhere, and if it were suggested that the principle was being carried too far and that there might be other effectual modes of treatment than the sanatorium, the suggestion was received with scoffing and the originator was regarded as one whose views were not worthy of consideration. So strong a hold had the belief in sanatorium treatment gained on the medical profession and the public that when the provisions of the Insurance Act in Great Britain were first drafted, that part of the act dealing with tuberculosis was designated "Sanatorium benefits," just as if no other treatment were necessary. Comment was made on this editorially in the MEDICAL RECORD at the time, and it was pointed out that Mr. Lloyd George had been badly advised if he had been led to believe that in the sanatorium lay the sole hope of eradicating tuberculosis. However, as remarked before, a most astonishing change has been manifested during the past year or so in the views of the medical profession regarding the treatment of tuberculosis and, of course, these views have been reflected in the revised drafting of the Insurance Act. The fact has been borne irresistibly upon the medical profession that it is not in sanatoria alone that salvation for the consumptive lies nor by sanatoria alone that the scourge will be stamped out. Indeed, it is now recognized the sanatorium is not even the main factor in the campaign against tuberculosis, but of more or less subsidiary moment. Chief reliance for both the eradication and the successful treatment of the disease must be placed upon dispensary and home treatment, and when the matter is considered it will be easily understood why this is so. In the first instance the ultimate eradication of tuberculosis can never be accomplished by treating those already infected and permitting the malady to spread unchecked. Moreover, it is wholly impracticable to prevent this spread by isolating every case. The reasons are obvious. There are too many patients and the duration of the disease is too long. In consequence the dispensary with its staff of doctors, nurses, and voluntary visitors must take all possible steps to prevent such spread. Furthermore, its rôle is to search out unsuspected cases and to provide them at once with proper treatment.

Therefore, the dispensary now takes its place in the front of the fighting line, it is the attacking force of the greatest strength and in addition is the first line of defence. The importance of the other parts of the army, the sanatorium, the open-air school, the hospital for advanced cases, and the hospital for surgical tuberculosis, is in no wise diminished. Rather their importance is increased and their work is rendered more efficient by having their proper functions marked out and by being linked together by the dispensary which will supply them with the suitable class of patient.

In Great Britain the honor of initiating and developing the dispensary system of treating tuberculosis is due mainly to Sir Robert Philip of Edinburgh, who has worked long in educating the medi-

*"Common Diseases," by Woods Hutchinson, A.M., M.D., author of "Strides in Human and Comparative Pathology," "Instinct and Health," "Preventable Diseases," "Handbook of Health," "We and Our Children," etc. Price, $1.50 net. Boston and New York. Houghton Mifflin Company, The Riverside Press, Cambridge, 1913.

cal profession as to the value of home and dispensary treatment. The Victoria Dispensary for the treatment of tuberculosis was opened in Edinburgh in 1887 and it was not until 1909 that the next one was opened in the British Isles. In New York most effective dispensary and home treatment of tuberculosis has been going on for some considerable time, but in Great Britain, undoubtedly, Philip of Edinburgh may be rightly termed the pioneer of this system of treating tuberculosis. Since the British Insurance Act was first mooted, the medical advisers of the Chancellor of the Exchequer appear to have undergone a change of front. The interim report of the Departmental Committee which was published recently is distinguished by a thorough recognition and appreciation of the value of the dispensary system of treating tuberculosis. The British Government has officially adopted an organized scheme similar to that in existence in Edinburgh as the fundamental basis of a national campaign against tuberculosis. By so doing the government has set the seal of its approval on the dispensary and home treatment of tuberculosis. As the matter stands now dispensary and home treatment, sanatorium treatment, hospital treatment for advanced cases, and hospital treatment for surgical tuberculosis, and tuberculin treatment all work hand in hand. Physicians now possess a proper sense of proportion with regard to the efficacy of different means of treatment, and as a body seem to be convinced that it is only by carrying out home and dispensary treatment to its utmost extent that tuberculosis can be stamped out.

---

### Symptomatic Scarlatina.

That a scarlatiniform syndrome can occur under various conditions from the pathogenicity of ordinary streptococci and staphylococci is well recognized. Supposed second attacks may no doubt be explained in part by this knowledge. In certain parts of the world a non-contagious, sporadic scarlet fever is known to exist. Surgical and puerperal scarlatina are doubtless chiefly symptomatic. The type under consideration differs in certain important respects from true scarlatina, aside from the communicable feature. The typical desquamation may be wanting, for example. But it must not be overlooked that irregularities in type may be in part attributable to the condition to which the scarlatinal syndrome has been superadded. At a recent medical meeting at Jena, Bennecke described several examples of a scarlatiniform syndrome accompanying typhoid (*Münchener medizinische Wochenschrift,* March 18). Complication of the latter with true scarlatina has never been seen at the author's clinic. Seemingly typhoid had so altered the resistance of the tissues that purulent foci present in the organism had become activated. In one case furunculosis coexisted, no doubt metastatic. The port of entry was probably the tonsil. Slight lacunar tonsillitis was present and staphylococci were found in the deposit and also in the pus of the furuncles. In another case otitis media was held responsible for the secondary affection. True scarlatina was excluded by absence of the Rumpel-Leede phenomenon. The presence of a mere aberrant typhoid exanthem was also out of the question.

## News of the Week.

**Vital Statistics.**—For the week ending April 5, the death rate in New York City was 14.68 per thousand, the total number of deaths being 1,512. For the same week of 1912, the rate was 17.05 and the total deaths numbered 1,691. The decrease occurred in practically all of the chief causes of death. For the first fourteen weeks of the year the death rate was 15.77, or slightly below that of the corresponding period of last year.

During the month of February there occurred in New York State 12,586 deaths, of which 703 were due to violence. An unusually large number also was due to diphtheria.

**Fall in the Birth Rate.**—The decrease in the French birth rate is again attracting attention, and a report from Paris states that the rate in 1912 was the lowest recorded since 1861. There was only one birth to every thirty families during the year. The infantile death rate, on the other hand, was increased to 143 per thousand. In the former year, with a population of 2,870,000, only 48,230 births were registered, this number being almost 5,000 less than in 1861, when the total population was little more than half as large.

**Centenarian Dead.**—Ocean Grove, N. J., reports the death on April 10 of its oldest inhabitant, John M. Butler, at the age of 103. Mr. Butler had been accustomed to drink eight cups of coffee a day.

**The Baby Show.**—The first hygienic baby contest held in New York on April 12 was a great success, and brought out a number of infants almost physically perfect. The first prize went to a German-Irish boy, who scored 99 points out of a hundred, and the second and third to a Russian and a Swiss girl respectively, with scores of 98.5 and 98. Eight babies received honorable mention with 97 points. All of which speaks well for the neighborhood in which the contest was held.

**The Friedmann Cure.**—Responding to an invitation from the Governor of Rhode Island, Dr. Friedmann left New York last week for Providence, where he has treated many patients and has been given the privilege of practising privately. Availing himself of this privilege, he made $2,000 in the first few days, according to *The Sun.* His sudden dropping of hospital experiments in New York and the alacrity with which the opportunity to make experiments for pay was seized upon tends to confirm the impression that it was not scientific ardor alone that impelled Dr. Friedmann to come to America. A death from tuberculous meningitis of one of the patients whom Dr. Friedmann had treated in New York, is being investigated by the surgeons of the Public Health Service.

**Bonds for Doctor's Fee.**—The Board of Estimate of the City of New York on April 10 approved the issue of $3,300 worth of special revenue bonds, which together with an unexpected balance of $2,500 in the city treasury, will suffice to pay the bill of the physician who attended Mayor Gaynor in St. Mary's Hospital, Hoboken, after the attempt on his life in 1910.

**Italian Hospital Open.**—The Italian Benevolent Institution and Hospital which has been erected in New York, facing the East River between 83d and 84th Streets, was opened recently for the reception of patients. The hospital contains 100 beds and also controls a dispensary in the immediate neighborhood. It is open to all patients, without regard to nationality.

**Plague in Colombia.**—The occurrence of several cases of bubonic plague at Santa Marta, Colombia, is reported in dispatches from Bogota.

**Lectures on Tropical Medicine.**—The Maryland University School of Medicine is offering a course of twenty lectures on tropical medicine under the supervision of Surgeon J. A. Nydegger of the U. S. Public Health Service. With the assistance of Dr. C. W. Stiles, Dr. H. R. Carter, and other members of the Public Health Service, Dr. Nydegger is giving a very comprehensive course.

**Meningitis on Warship.**—Reports of an epidemic of meningitis on the battleship *California* at Guaymas, Mexico, were received by wireless at San Diego, Cal., on April 12. The message requested that a supply of anti-meningitis serum be sent to Guaymas immediately, and the destroyer *Paul Jones* was at once started southward carrying a sufficient quantity of the drug.

**School Hygiene.**—The Fourth International Congress on School Hygiene will be held in Buffalo, N. Y., on August 25 to 30, under the patronage of the President of the United States. At this congress—the first of its kind ever held in this country—it is desired to bring together men and women interested in improving the health and efficiency of school children, and to that end a comprehensive programme of papers and discussions covering the entire field of school hygiene is now being arranged. There will be in attendance delegates from all the leading nations and from every college and university of note in this country, as well as from many educational, medical, and hygienic organizations. Membership in the Congress may be secured on the payment of a five dollar fee, and applications may be made to Dr. Thomas A. Storey at the College of the City of New York, N. Y.

**A Missionary Nurse Wanted.**—The American Hospital for Women and Children at Madura, South India, is in need of a graduate nurse to serve as hospital superintendent. The hospital contains fifty beds, and during 1911, in both the wards and the out-patient department, 12,364 patients were treated. The staff consists of two American physicians with Indian assistants, and the aid of an American trained nurse is greatly desired. The salary of the superintendent is $500 a year, together with a room in the mission bungalow. Further information may be obtained from Mr. W. B. Smith, 600 Lexington Avenue, New York.

**Radium Treatment.**—A department for treatment with radium emanation has been established at the New York Post-Graduate Medical School and Hospital, for public use and scientific investigation.

**X-Ray Suits.**—The Supreme Court of the United States on April 8 handed down the first decision it has ever rendered covering suits for damages for injuries resulting from the use of the *x*-ray. The justices hold that in such cases the burden is on the plaintiff to show that the defendant, a physician in the case under consideration, was negligent, and that the physician need not prove that he was not negligent. The decision was made in a case brought by a patient against a physician in Washington, the patient claiming damages for burns caused by treatment with the *x*-ray.

**Gifts to Charities.**—The German Hospital of Brooklyn and Mount Sinai Hospital of New York receive $2,000 each, and the Montefiore Home $1,000, by the will of the late Joseph Liebmann of this city.

By the will of the late Ellen Connor of New York bequests of $500 each are made to the Home for Consumptives and the New York Foundling Hospital.

By the will of the late Anna S. Reed of Philadelphia the sum of $1,000 is bequeathed to the Women's Homeopathic Hospital.

**Personals.**—Dr. Michael J. O'Meara of Worcester, Mass., has been elected chairman of the Massachusetts State Board of Health.

Dr. John G. Towne of Waterville, Me., has been made commissioner major and surgeon in the Medical Corps of the National Guard of the State.

President Wilson has followed precedent in accepting the presidency of the American Red Cross.

**The Henry Phipps Psychiatric Clinic** of Johns Hopkins Hospital for the treatment of mental disorders was formally opened on Wednesday afternoon of this week. The opening address on "Specialism in General Hospitals," was delivered by Sir William Osler.

**Medical Society Elections.**—Bienville Parish (La.) Medical Society.—At the annual meeting held in Arcadia on April 1, the following officers were elected: *President*, Dr. Oliver O. Hanner, Bienville; *Vice-President*, Dr. J. M. Mosely, Arcadia; *Secretary-Treasurer*, Dr. Edwin O. Edgerton, Arcadia.

Somerset County (Md.) Medical Society.—The annual meeting of this society was held in Crisfield on April 2, and the following officers were elected for the ensuing year: *President*, Dr. Gordon T. Simonson, Crisfield; *Vice-President*, Dr. Martin W. Goldsborough, Princess Anne; *Secretary-Treasurer*, Dr. Henry M. Lankford.

Golden Belt (Kan.) Medical Society.—The following officers were elected at the annual meeting of this society held at Junction City on April 3: *President*, Dr. Richard C. Lowmare, Kansas City; *Vice-Presidents*, Dr. William E. Mowrey, Salina; and Dr. Peter W. Beckman, Lindsborg; *Secretary*, Dr. Walter A. Carr, Junction City; *Treasurer*, Dr. James C. Wilhoit, Manhattan.

**The Late Dr. Francis.**—At a special meeting of the Executive Committee of The Associated Physicians of Montclair, N. J., and vicinity, held March 30, 1913, on account of the death of Dr. Richard P. Francis, the following resolutions were adopted: Whereas it has pleased Almighty God to remove from our midst the friend and associate whom we all deeply mourn, be it resolved: That in the sudden death of Dr. Francis this Society and the community in which he lived have sustained the loss not only of a skillful practitioner of medicine, but also of a most genial and cultured gentleman. That the heartfelt sympathy of the members of this Society are hereby extended to his family, whom we pray may be given strength to bear up under this sad affliction. That a copy of these resolutions be engrossed and presented to his family, and that they be also published in the local press, the Medical Record, and the *Journal of the Medical Society of New Jersey*.

**Obituary Notes.**—Dr. Jared Grover Baldwin of New York, a graduate of the New York University Medical College in 1853, a member of the American Institute of Homeopathy and the New York County Homeopathic Medical Society, and consulting physician to the Hahnemann Hospital, New York, died at his home, after a lingering illness on April 11, aged 85 years.

Dr. Edward Pepper, formerly of Philadelphia,

died at his villa in Algiers during the last week of March. He was a graduate of the École de Médecine of Paris, and he practised his profession in Paris and in Algiers.

Dr. Edwin Folsom of Fargo, N. D., died at his home on March 22, aged 71 years.

Dr. John Edwards of Gloversville, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1869, a member of the New York State and Fulton County Medical Societies, visiting physician to the Nathan Littauer Hospital, Gloversville, and for many years health officer of the town, died at his home on April 4, aged 66 years.

Dr. Frank Little of Brooklyn, N. Y., a graduate of the University of Worcester, Medical Department, in 1881, a member of the American Medical Association, the New York State and Kings County Medical Societies, the American Electro-Therapeutic Association and the Brooklyn Pathological Society, and formerly on the staff of the Kings County Hospital, died at his home on April 4, aged 57 years.

Dr. George Allen Staples of Dubuque, Iowa, a graduate of the College of Physicians and Surgeons, New York, in 1885, and a member of the American Medical Association, the Iowa State and Dubuque County Medical Societies, the Chicago Orthopedic Society, and the American Pediatric Society, died suddenly of apoplexy, on April 2, aged 54 years.

Dr. Karl G. Morse of Boston, Mass., a recent graduate of the Tufts College Medical School, Boston, died in a Boston hospital on April 3, aged 26 years.

Dr. Algernon S. Barnes of St. Louis, Mo., a graduate of the Medical Department of the University of Missouri, Columbia, in 1855, a veteran of the Civil War, during which he served as surgeon in charge of the Military Hospital at St. Louis, and a member of the American Medical Association and the Missouri State and St. Louis City Medical Societies, died at his home on March 30, from arteriosclerosis, aged 82 years.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

APPENDICITIS; DIAGNOSIS, BASTEDO'S AND ROVSING'S —ANESTHETICS, DEBATE ON—A TRAVELING EXHIBITION—GUILD OR UNION—OBITUARY.

London, March 28, 1913.

Dr. A. F. Hertz, assistant physician to Guy's Hospital, brought before the Royal Society of Medicine on the 14th inst. the symptom of chronic appendicitis first described as a test by Dr. Bastedo of New York. This symptom, the production of pain and tenderness in the right iliac fossa on inflation of the colon with air, Dr. Hertz has employed in a number of cases and found it of such value that he is anxious it should be more widely recognized. It is simple to carry out, he says, causes little inconvenience to the patient and is in his experience more reliable than any other sign. He uses an ordinary rubber rectal tube which he only introduces about 1½ inch from the anus, contrary in this to Bastedo's proposal to pass it 11 or 12 inches; for there is no advantage in passing it further than just beyond the ampulla, as experiments he has made with Dr. Goodhart and others show that a tube can very rarely be passed beyond the pelvi-rectal flexure which is never more than 6 inches from the anus.

When air is slowly pumped through the inflation tube the colon is seen to become distended and soon a diffuse discomfort is felt by the patient in the lower part of the abdomen but no pain, unless a great quantity has been forced in, and even then it is not more marked on one side. Further, no tenderness is produced in the absence of appendicitis. But pain and tenderness are produced in the right iliac fossa when chronic appendicitis is present. When tenderness has previously been observed it will be aggravated and when it has not been detected in spite of frequent examinations inflation will produce it. Dr. Hertz has noticed an additional symptom, viz.: pain referred to the epigastrium on pressure in the right iliac fossa after inflation. He has only employed this sign in suspected chronic cases. Mr. Sheaf tried it in two acute cases but was prepared to operate instantly if the test were positive, as it proved, and excision was performed in both cases within a few minutes. This precaution is most necessary in acute cases and to it may be added care to introduce the smallest quantity of air, just enough to increase slightly the pain. Otherwise there would be danger of tearing adhesions or causing perforation of a diseased appendix.

Another sign, commonly called Rovsing's, although it was employed before he wrote of it by Dr. Lauriston Shaw, may be mentioned as probably dependant on a similar condition. It consists in pain in the right iliac fossa on making pressure over the descending colon, probably due to gas being forced from the distal into the proximal portion. Its use is very limited as it is rare for gas enough to produce it to be present in the descending colon.

At the meeting of the Section of Anesthetics an address on Clover as a pioneer and surgical inventor was delivered by Mr. Buxton Browne who began by expressing his pleasure that the Section accepted his presentation of Clover's portrait. It was only natural for a general surgeon to dwell on Clover's contributions to the surgical art more than on his pioneer work. One of the nineteenth century's greatest boons to humanity was lithotrity, but that was not perfect until Clover's evacuating bottles and tubes completed it. Many modifications have been suggested but all have been abandoned and Mr. Browne said he would be content to use it just as it left Clover's hands if he had to perform lithotrity to-day. The last century was the most marvelous the world has seen in reference to the progress of surgery and Mr. Browne thought British surgeons led the van of that army of progress, but only about a dozen were originators who left an abiding mark on practice, as Clover did, and who was therefore rightly called a genius. Dr. Dudley Buxton and Mr. B. Gardner also eulogized Clover who was the first in England to apply a face piece in administering nitrous oxide, which he demonstrated at the Dental Hospital in 1866.

A paper on technique in general anesthesia for intranasal operations was then read by Mr. Bellamy Gardner who laid down principles for agreement between surgeon and anesthetist and held a patient might be anesthetized in the sitting posture by the skilled specialist. This was discussed by Messrs. Barton, McCardie and Boyle who found surgeons differed a good deal as to the position they preferred for the patient during these operations.

Two papers followed on the use of scopolamine, morphine, and atropine combined. The first by Mr.

Morcom who recommended an injection of this mixture three-quarters of an hour before an operation, the usual effect being that the patient falls into a quiet sleep and the general anesthetic can be given without waking him and in less quantity. The dose he gave was hyoscine hydrobromide, 1/120 grain; morph. tartrate, 1/6 gr.; atropine sulph., 1/100 gr. Subsequent vomiting was practically non-existent, say 6 per cent. The second paper was by Mr. Lionel Norbury who gave the injection two hours before the operation, containing 1/75 gr. hyoscine hydrobromide, morph. tart. 1/6 gr., and atrop. sulph. 1/150 gr. This was usually sufficient, but if not he gave, fifteen minutes before the operation, an injection of ¼ gr. morphia only—a safer plan than repeating the compound. He had only tried the plan in six cases and in three of them he added local infiltration of the skin with a 1 per cent. solution of novocane; in one he gave a little gas for the preliminary incision, the subsequent proceedings being carried in comfort—no shock, no pain, the patient sleeping on for hours. The respirations fell to 8 and were Cheyne-Stokes in character, but responded to an injection of strychnine. The injection seemed of most value in amputation, in cases of diabetes, phthisis, sepsis, or cardiac or arterial disease, as it caused no shock and no danger of acidosis or coma.

The President, Dr. Blumfeld, said surgeons were not agreed as to the value of scopolamine, some objecting that it caused rigidity. He had observed it sometimes delayed relaxation. Patients were grateful for it, but it did not detract from the difficulties of the surgeon or anesthetist. He was using it in combination with omnopon and atropine. Dr. Tate did not think it impeded the surgeon but a quieter time was secured after the operation. Dr. Powel said nurses thought it more difficult to tell if the patient were in danger after scopolomine. Dr. McCardie saw no need for the atropine; of course the morphine made matters easier for the surgeon by damping down the respiration. After these alkaloids there seemed more oozing than without them; he gave a fairly full dose before ether inhalation. Dr. Wilson remarked that young patients who had had morphine before general anesthesia often experienced excessive thirst afterwards.

The Traveling Tuberculosis Exhibition which for many months has been going through the towns of the country to disseminate knowledge concerning the prevention of the disease has been staying all this week at Poplar. Arrangements were made for admitting the school children to the extent of some 300 a day, and a sum of £75 was presented to the Poplar Dispensary to provide 100 prizes for the children writing the best essays on what they saw and learned at the exhibition. The dispensary was opened last April and 964 persons have since applied for treatment, of whom 509 had pulmonary phthisis, 194 were grouped as suspects, and 264 were non-tubercular.

The National Medical Guild, recently formed, has applied to be registered under the Trades Union Acts and is issuing a circular inviting all practitioners to join and so secure a powerful body to defend their interests. The Guild will resist the arbitrary powers which are being assumed by the Insurance Commissioners and will not be above employing trade union methods if the necessity of doing so is forced upon it. Mr. Charles Buttar, an earnest worker, is the president.

The Guild must be distinguished from the union formed some eighteen months ago and composed of men who decline to go on the panel or having done so have found it impossible to work the system with benefit to the patients and will retire at the end of the first term, next month. The Union will work for an amended act but will not adopt trade union methods.

Dr. Galabin, Conulting Obstetric Physican to Guy's Hospital, died on the 25th inst. at his country residence, after five days illness, from pneumonia. He graduated as a Wrangler and first-class Classic at Cambridge, in 1866, and proceeded to M.D., 1873, as gold medallist of his college (Trinity). He had meantime taken the curriculum at Guy's and the membership of the two Royal Colleges. He was elected F.R.C.P. in 1878. He has been President of the Obstetrical Society, also of the Hunterian Society, and Examiner to the Universities of Oxford, Cambridge, and London. For a time he edited the *Obstetrical Journal* and contributed freely to the *Transactions* of the societies and *Guy's Hospital Reports*. His *Manual of Midwifery* and his *Diseases of Women* both passed through several editions. Among other subjects he wrote about the cardiograph, the cause of water-hammer pulse, and secondary waves of the pulse.

Another gynecologist, Dr. A. J. Wallace of Liverpool, has died at the early age of 46, but not before he had made his mark in the profession and in his specialty. He graduated at Edinburgh in 1889. He became lecturer on his subject at the Liverpool University College, where he held a scholarship, and surgeon to the Hospital for Women and the Maternity Hospital, and consultant to the Royal Southern Hospital. He contributed valuable papers to the societies and journals.

Brigade-Surgeon C. F. Oldham, I.M.S., has died in his 82d year. He qualified at the two colleges in 1858-9. He wrote "What is Malaria?" and also "The Sun and the Serpent."

Dr. Peter Anderson, for over thirty years medical missionary in Formosa, died on the 12th inst. in his Scottish home, to which he retired some three years ago. He took the two diplomas of the Edinburgh Colleges in 1878 and sailed for Japan soon after, as he had qualified with the express intention of becoming a missionary.

## OUR PARIS LETTER.

(From Our Regular Correspondent.)

COMPULSORY NOTIFICATION OF TUBERCULOSIS—DANGER OF CONTAGION FROM TUBERCULOSIS IN THE HOSPITALS—OFFICERS OF THE ACADEMY OF MEDICINE—AIR EMBOLISM FOLLOWING PROSTATECTOMY.

PARIS, March 1, 1913.

THE question of the compulsory notification of cases of tuberculosis came up before the Academy of Medicine as the result of the initiative taken by certain members of Parliament who have the courage to propose the defense of the country against tuberculosis. This question has already come up for discussion on many occasions. At the present time the reporting of cases of pulmonary tuberculosis is optional. According to Professor Letulle, who opened the discussion, tuberculosis is the most deadly of the transmissible diseases although the modes of contagion are perfectly known. Moreover, the distress which it causes and its profound economic influence make it the most important of the social diseases. The obligation of reporting a case of tuberculosis should devolve upon the head

of the family who should be provided with a certificate by the physician treating the case. In order that the spread of tuberculosis may be effectively combated, it is necessary to take arms against alcoholism, unhygienic dwellings, and the adulteration of foods. The people should be guaranteed a healthful and inexpensive diet and should be given the opportunity of working among the best hygienic surroundings.

Professor Robin does not believe in making the notification of tuberculosis compulsory, on account of the difficulties that would attend the enforcement of such a measure. He believes that it would suffice to compel the disinfection of the premises following the death of a case of tuberculosis, and possibly after the removal of a tuberculous patient to another dwelling. Reynier also believes that compulsory notification would be of questionable value from the viewpoint of prophylaxis. All the measures necessary for disinfection and curative treatment can be carried out without subjecting the patient and his family to the vexation of being reported to the public authorities. He proposed that the Academy should recommend that all vacant dwellings be disinfected before being rented to new tenants. Regarding alcoholism as one of the most important factors in the production of tuberculosis, he advocated a strict enforcement of the law relative to the limitation of the number of saloons and the regulation of the sale of alcohol. Lereboullet believes that a successful campaign against tuberculosis would demand the better sanitation of dwellings, the repression of alcoholism, and the extending of the necessary social aid to indigent consumptives.

Professor Gaucher thinks that the compulsory notification of tuberculosis is impracticable, vexatious, and useless. Moreover, it could not be enforced, for the physicianu who fails to report a case may allege in self-defense that he has made an error in diagnosis. Mosny declares that the proposed law has been opposed by nearly the entire profession. The ideal methods of prophylaxis would be the isolation of the tuberculous in rooms sufficiently spacious to minimize the risk of contagion, the sending of all susceptible children to the country, the aiding of the families of the afflicted, and the periodical disinfection of the linen, the clothing, and the dwelling of the patient.

Professor Widal alluded to the fact that most of the tuberculous cases came sooner or later to the hospital or dispensary, and that the reporting of these cases took place automatically. Contagion was most to be feared in the hospitals in which patients with tuberculosis were treated promiscuously with other patients. The latter who were enfeebled as the result of acute or chronic disease were most susceptible to tuberculosis. The speaker advocated the provision of special wards for tuberculous patients. Heurot of Rheims called attention to the fact that of all European nations France leads in the percentage of tuberculous cases among its population.

Mesureur, Director of Public Charities, hoped that the debate would put an end to the uncertainty that has prevailed regarding the means of preventing contagion in the hospitals. The isolation of the tuberculous patients would necessitate the use of a distinct hospital equipment for these cases and the organization of a separate medical staff.

The officers of the Academy of Medicine have been installed for the present year. The president is Professor Chauveau, an eminent savant, honored in France and in other countries, and regarded as an authority in many fields of medical science. The vice-president is Dr. Perier. The permanent secretary is Professor Jaccoud, and the annual secretary is Professor Blanchard.

At the Surgical Society, Marion reported a case of prostatectomy in which the patient died from air embolism. Following anesthetization an assistant filled the bladder with air, according to the usual method, but to the surprise of those present 450 c.c. of air were injected without distending the bladder. The operation was carried out in the ordinary way: the prostate was enucleated after the bladder was opened and the patient was returned to his bed. A few minutes later he died, his skin having taken on a marked violaceous coloration. Marion believes that the fatal outcome in this case is to be attributed to air embolism, the injection of air having caused a laceration of the vesical mucosa, with the production of an opening in a vein through which air entered. The speaker believes that the danger of embolism may be avoided by the use of a fluid in distending the bladder.

## OUR BERLIN LETTER.

(From Our Regular Correspondent.)

STATISTICS RELATING TO THE MEDICAL PROFESSION OF GERMANY—THE PROPORTIONS OF SPECIALISTS—GLOOMY OUTLOOK—NATURE OF ARTHRITIS DEFORMANS—STATISTICS OF FERTILITY.

BERLIN, February 15, 1913.

THE statistics of Prinzing relating to the medical profession of Germany have, as usual, appeared punctually. In 1912 there were in Germany 33,527 physicians, or 5.06 to every 10,000 inhabitants. There was a decided increase over the previous year. There is a relatively small number of physicians in the industrial kingdom of Saxony, in the Rhenish provinces, and in Westphalia. This is naturally due to the fact that there are in these regions a particularly large number of state invalidity insurance offices, which afford to only a few physicians the prospects of a good livelihood. There are 151 female physicians, of whom 124 live in large cities. There has been a marked increase in the number of female medical students, which amounted to 582, as against 371 of the previous year. There has been a slight decrease in the number of specialists. In 1911 there were 35.9, while in 1912 there were 35.5 to every 100 physicians. The gynecologists predominate; next in order come the surgeons, the ophthalmologists, the laryngologists, the dermatologists, and the pediatrists. If one take into account the marked increase in the number of students, the outlook for the German practitioner is getting worse and worse.

The "Nature of Arthritis Deformans" was the subject of a discourse by Axhausen at the first meeting this year of the Berlin Medical Society. None of the theories that have been proposed concerning this disease have been satisfactory. The real cause, according to the speaker, is a bony necrosis which causes a reactive inflammation in the surrounding tissues. The form of the resulting bony changes is determined by the static conditions. Changes similar to those present in this disease can be produced experimentally. By means of electrolysis there can be produced a necrosis in the healthy articular cartilage. There then result arthritic manifestations that closely simulate those present

in arthritis deformans. How can one explain the greater incidence of this disease in advancing life? Cartilage receives its nourishment by diffusion. If nutritional disturbances occur in an individual passed middle life, then the conditions for necrosis are present, and the clinical picture of arthritis deformans readily unfolds itself.

At the close of the last year F. A. Theilhaber read a paper before the Society of Social Medicine, Hygiene, and Medical Statistics. The title was "New Statistical Methods in the Determination of Fertility." The speaker emphasized the fact that former methods of calculating fertility on the basis of an excess of births were false. The excess of births is no definite indication of the degree of fertility. The error in the former methods consisted in the fact that the degree of fertility depends not only upon the excess of births but also upon the death rate. Now, it might happen in certain localities, that the mortality would become nil, provided that all aged individuals moved away from these localities. Besides, a recent youthful immigrant population has a very low death rate. Theilhaber reaches the conclusion that the excess of births obtained by the subtraction of the general death rate from the birth rate is so dependent upon the national peculiarities, the health of the older classes, the infantile mortality, migrations, and other factors, that the figures obtained are not indicative of the degree of fertility. Adopting the suggestion of Hindelang, the speaker employed the following method of solving the problem: If 1,000 fertile women are mated with 1,000 fertile men there will be 66.7 births per year. Since the reproductive period extends from the fifteenth to the forty-fifth year, there should be a total of 2,000 births during this period. The figure 66.7 per thousand represents the ideal increment of births. This ideal, however, does not give the exact figures, for up to the time that the females reach the reproductive age, say the fifteenth year, a certain proportion die. This proportion is subject to but slight variation, and may be easily calculated. The mortality up to five years is 20 per cent. of all births; the mortality from five to fifteen years is 5 per cent. of the births. The total mortality is 25 per cent., on account of which the ideal increment of births must be increased in order to assure the maintenance of the normal increment of birth. The increased figure for the ideal increment should be 89 births per 1,000 child-bearing women. According to this method, it is found that in 1906 the French nation gave evidence of a substantial degree of fertility. In 1909, however, the latter was represented by the figure 87.5 per 1,000, which, on comparison with the normal figure of 89 per 1,000, shows that the fertility was 1 per cent. too small. After presenting a number of other examples the speaker concluded that his method provided a scientific means of measuring the fertility of a people.

5. The Etiology of Hay Fever. T. Smith.
6. A Case of Gastromesenteric Ileus. C. A. Porter and G. W. Morse.
7. Syphilis and the Surgical Out-Patient. W. P. Coues.

1. **Urinary Excretion of Formalin in Children.**—F. B. Talbot and W. R. Sisson conclude from their observations that all children are capable of breaking down hexamethylenamin and that they all consequently excrete formaldehyde. Relatively large doses are often necessary before the excretion of formaldehyde takes place. As pointed out by Jordan, "the more acid the urine the greater is the decomposition of urotropin and excretion of formaldehyde." Since it has been shown by other observers that the antiseptic power of urotropin is dependent, not upon the hexamethylenamin, but upon the presence of free formaldehyde, one can further conclude that urotropin should not be given with drugs that cause the urine to turn alkaline. Finally, the authors believe that to insure the efficacy of the drug, specimens of urine after the administration of hexamethylenamin should always be examined for the presence of free formaldehyde.

2. **Spontaneous Recovery from Coxa Vara.**—J. W. Sever notes that rachitic coxa vera is frequently associated with bow legs and knock knees, but may exist independently. In the author's series of cases it was observed to a greater degree in knock knees than in bow legs. The condition apparently requires no treatment. The correction of a co-existing condition of knock knees or bow legs may hasten the process of recovery from coxa vara. In all cases there is a tendency to spontaneous recovery and a restoration towards the normal angle of the neck of the femur without treatment. There is probably very little or no permanent disability in the average case.

3. **The Wassermann Reaction in the Insane.**—H. L. Paine states that of 200 consecutive insane patients admitted to the Danvers State Hospital 49 showed a positive Wassermann reaction, *i.e.* 24½ per cent. One hundred and forty-six cases were from cities; of these, 36 gave a positive reaction, a percentage of 24+. Fifty-four cases were from towns; of these, 13 were positive, a percentage of 24+. Of these 200 cases, 118 were males, and of these 30 were positive, a percentage of 25+. Eighty-two cases were females, and of these 19 were positive, a percentage of 23+. The seacoast cities gave a percentage of .32; the inland towns gave a percentage of .17; the mill cities gave a percentage of .28; and other cities a percentage of .19.

5. **Etiology of Hay Fever.**—T. Smith finds that it is not quite possible to explain definitely hay fever as an effect of pure toxins on the one hand, or of hypersensitiveness on the other. The latter explanation is the simpler and is currently accepted. Not enough, however, is known of anaphylaxis itself. There are many phenomena at present thrown together as anaphylaxis, which need further analysis. It is also probable that in this disease the two phenomena are so associated that now one, now the other predominates. Pollen protein may contain both hypersensitizing and toxic substances not yet separated from one another.

7. **Syphilis and the Surgical Out-Patient.**—W. P. Coues believes that there is an enormous amount of unrecognized syphilis in the surgical out-patient department of hospitals and dispensaries in every large city. The prompt recognition of these cases for their own benefit and that of their community is of great importance. They should at once be referred to and treated by those in charge of the department for syphilis in the various institutions. Every such out-patient department should have facilities for treating all the manifestations of syphilis, surgical, or otherwise, within its own walls. In the surgical department three minutes extra time spent with each patient will show the presence or absence of keratitis, gum-

matous scars, gross periostitis of the long bones, abnormal teeth, old perforations of the palate, or lesions of more active syphilis, and will repay the surgeon for his trouble.

**2. Vienna as a Center for Postgraduate Medical Study.**—A. Maverick calls attention to those American students who "waste their time and money and sometimes fool their friends at home by 'studying abroad.' 'That doctor studied in Vienna, he must be pretty bright.' Yes, but what did he study? Here is one disciple of Esculapius who studied diseases of the eyeball three hours a week and the peculiarities of the billiard ball six hours a day—he will soon return as an eye specialist. Here is another who is taking up genitourinary diseases, but who hunts for gonococci, not in the hospital, but in cafés and music halls. Here is a third who will soon open an office in a large American city as an expert on stomach troubles, but whose study has consisted chiefly in the effects of Hungarian goulash and Munich beer upon his own stomach. Here are some more who do not maintain that they are studying anything—they are 'just looking around, getting used to the language and customs before beginning.' Many of these do not know exactly what they want. Then there is the busy practitioner who rushes through Vienna with exactly six weeks to spare. He expects to gulp down a dose of foreign medicine as he would a cup of coffee and a fried egg. Mental indigestion is the result. He would do better at home, Maverick says, keeping up with his medical journals.

**3. Congenital Word Blindness.**—B. Chance notes that an analysis of the published cases of this condition shows that a great variety exists; some of the patients were "blind" for letters or for only certain letters; others were "blind" for certain words only, or, for the order of the letters in the words; while others were not able to read words at all. The author has not seen a case of complete inability to recognize letters—"literal alexia" must be rare indeed. Very few, with the advance of their intelligence, failed to learn to read arithmetical signs and figures; evidently that was because figures have complete mental values, whereas letters and even words are not entities and require therefore a context to impress their meaning. That all the cases should have been found, with two or three exceptions, in boys, and not in girls, and always in youths of British or American birth or descent, is one of the unexplained mysteries, Chance says, of this curious affection.

**9. Types of Continued Fever.**—W. Allan states that in the Piedmont region of North Carolina more than half of the typhoid fever cases exhibit a low remittent temperature and that the duration of fever after admission to the hospital was less than fifteen days in 53 per cent. of the cases. These cases were practically all seen during the first week of illnesss, so that the short duration of fever and the remittent curves are not due to late admission during the third and fourth weeks. However, the mortality of the low remittent typhoid in this series (10 per cent.) is not less than the general mortality. The preponderance of these short and often mild cases is probably due to a liberal admixture of paratyphoids.

13. Intermittent Pyuria Due to Infection of the Prostatic Utricle. A. J. Underhill.

**1. Ligneous Phlegmon of the Abdominal Wall.**—W. W. Grant reports two cases of this condition in which staphylococcic infection was determined. The cancerous theory will probably soon be abandoned, and, according to present knowledge one is justified in concluding that the disease generally occurs after middle life in persons whose resistance has been impaired by previous ill health. The immediate cause is a slow infective process with or without trauma. The dictum of Reclus that it is not due to specific bacteria, but to a variety of germs of mild virulence seems confirmed. The staphylococci seem to be the chief offenders. The usually slow and protracted course and final resolution are characteristic. Hyperleucocytosis always exists. The disease is cured more quickly and completely by free incision and serum treatment than by any other means known at the present time, and early diagnosis makes the relief more frequent and rapid.

**9. Familial Dextrocardia.**—S. Neuhof reports two cases of this condition observed in a brother and sister. No such condition existed in the parents, as far as is known, or in the one living brother. In the girl, who died from tuberculosis some years ago, the hospital report reads, "Heart situated on the right side, liver on the left." In the male the same conditions exist, the apex of the heart being located in the fifth intercostal space on the right side. The liver is situated on the left, the spleen on the right. The man is a hard worker and suffers from no circulatory disturbances.

**10. Arthritis in the Canal Zone.**—W. Baetz believes that cases of acute arthritis are often diagnosed as acute articular rheumatism. The existence of the latter in the tropics has been denied, and to gain information as to the types of joint affections occurring among the colored employees of the Canal Zone, a study of 100 consecutive acute cases was made by him. Traumatic cases and those occurring in pyogenic and disseminated tuberculosis were excluded. The patients were adult male negroes in the Ancon Hospital, and it is not probable that any of them except one have ever lived anywhere outside of the tropics. The final diagnoses were as follows: Syphilitic arthritis, 63; gonorrheal arthritis, 28; undetermined arthritis, 6; dysenteric arthritis, 2, and tuberculous arthritis, 1. The large proportion of syphilitic cases was determined, not by clinical observation alone, but also by the Wassermann and therapeutic tests, the former of which was positive in 93.6 per cent. of the sixty-three cases.

**11. An Early Symptom in Rabies.**—M. B. Wesson calls attention to an early symptom of rabies observed by him in animals and man which has received very little notice in literature. This is a left hemiplegia, starting in a hind leg in the lower animals and simulating Landry's paralysis. He has observed this symptom in over two hundred rabbits inoculated with rabies, as well as in a number of animals infected otherwise. He also had the opportunity of observing a fatal case in man in which this symptom occurred. It has been noticed in man, the hog, the dog, the guinea-pig, and the rabbit; in all of the quad-

rupeds the initial paralysis was in the left hind leg and in the man it was in the left leg and gradually developed into a left hemiplegia which later became general. The author concludes that in an animal that has suddenly become extremely nervous and irritable the development of a weakness in the left hind leg without apparent cause warrants a tentative diagnosis of rabies.

13. **Intermittent Pyuria.**—A. J. Underhill reports two cases of intermittent pyuria diagnosed as due to infection of the prostatic utricle. In each case the posterior examination of the urethra through the endoscope showed the verumontanum swollen and edematous and pus could be washed out from the utricle. The condition was relieved by injections of 1 per cent. silver nitrate and in the second case by the same, later replaced by quickly withdrawn injections of a 1:1000 solution of liquor formaldehyde. The point of interest in the cases was the intermittent pyuria lasting a day or so and followed by a disappearance of all symptoms during the intervals until sufficient pus accumulated for the pressure to overcome the resistance offered by the adherent opening to the utricle. Another point of interest in the second case is the fact that the ejaculatory ducts opened into the utricle, as spermatozoa appeared every time it was aspirated. It is surprising that the seminal vesicles and the epididymis were not also infected more severely than was the case.

6. The Individual Treatment of Diabetes. S. A. Arany.
7. The First 100 Cases Recommended for Sanatorium Benefit in East Essex.

1. **Intrathoracic Aneurysm.**—F. de Havilland Hall states that the sphygmograph is a useful adjunct in the diagnosis of this condition. It will enable a definite record to be kept of the condition of the pulses, and if there be any difference between the two pulses the tracing will give more distinct information than the impression conveyed to the finger. It is a curious circumstance that in the past so little attention was paid to miosis. Tracheal tugging may be present when many other physical signs and symptoms are absent. The sign is limited to aneurysms involving the transverse arch. Direct pressure upon the trachea does not cause tracheal tugging. In no department of medicine has the *x*-ray method of examination done greater service than in the detection of intrathoracic aneurysm. In speaking of the mode of termination of intrathoracic aneurysm the author mentions the possibility of cure, though this termination is seldom met with. In the rare cases in which cure of an aneurysm takes place this is effected in one of two ways: either by the deposition of laminated fibrin in the interior of the sac, or by the outer coating of the sac getting more and more supported externally, by fibrous change taking place in the tissues around the aneurysm. A fatal termination may be brought about in the following ways: I. Rupture: (*a*) Internal—(1) into serous membranes; (2) into mucous membranes; (3) into blood-vessels; (4) into the subcutaneous tissue. (*b*) External. II. Pressure upon trachea. III. Pressure upon esophagus. IV. Exhaustion due to long-continued suffering, or arising from repeated small losses of blood. V. Heart failure—frequently in connection with aortic regurgitation. VI. Anginal attacks. VII. Cerebral embolism. VIII. Pulmonary tuberculosis and other complications.

2. **Eczema Oris and Congenital Syphilis.**—L. Findlay and H. F. Watson state that in its most typical form the lesion is situated at one or both angles of the mouth and radiates therefrom towards the cheek, sometimes in the form of fan-shaped patches. It may, however, completely surround the mouth and implicate the face extensively. The patches are somewhat irregular in shape with sharply cut or ill-defined margins. They are red in color, at times the hyperemia being very marked. The surface is, as a rule, dry and scaly, although occasionally, and especially during an exacerbation of the mischief, there may be some discharge with the formation of crusts, and at this period there is always a certain degree of induration. The eczematous patch is continuous with, and frequently invades, the mucous membrane of the lip, giving it a slightly papillary appearance. The lips themselves may be swollen to a greater or less degree. A similar condition round the nostrils, where there is usually a greater tendency to moisture, and eczema tarsi are also present in a proportion of the cases. It is a most obstinate and chronic malady, never entirely disappearing, though varying much in severity from time to time.

3. **Puberty, the Menopause, and Neurasthenia.**—H. Macnaughton-Jones asks: "To what conditions should one limit the application of the term pubertal neurasthenia," in which he includes the borderland symptoms of psychasthenia. He groups these symptoms as follows: complaints of fatigue and disinclination to work and recreation, with general apathy; irritability of temper and capriciousness; inability to concentrate attention; neuralgias; erratic and shifting pain in the head, spine, and left intercostal region; capriciousness in or morbid appetite; gastric neurosis, and urinary irritation and frequency. Following these psychophysical symptoms come the more purely psychic, morbid imaginings and causeless apprehensions, fanciful ailments, groundless resentments and dislikes of relatives or friends, unconquerable erotic impulses, and religious fervor and obsessions. As regards neurasthenia of the menopause the first important practical point is the differentiation of those symptoms which are common to the climacteric and in no sense appertaining to true neurasthenia. Both during the advent and occurrence of the menopause women vary greatly in their powers of endurance of pain and self-control, and in their sensitiveness to any reference to the sexual change. With it come various vasomotor disturbances, morbid blushes, flushings, attacks of giddiness, tinnitus, retinal hyperemias, laryngeal neuroses, coldness of the extremities, headache, general languor, ovarian, sacral and coccygeal pain, palpitation, breathlessness, cardiac intermission, digestive errors, and urinary changes. It is only natural that, when any such exciting or depressing causes exist, irritability, or some erraticism of temper, demeanor, conduct, or the assumption of an unusual attitude to friends should occasionally declare itself. It is at such times that the suggestion of some slighting term as "neurotic" becomes unjust and cruel. Any of these states may become aggravated and merge into attitudes of inaptness and irresistible fatigue, of excitability and irritability, or nervousness and apathy, of apprehension and brooding, of antipathies and unwarrantable inferences, together with obsessions as to various ailments and pains, or the fear of the committal of some wrong and sin. Then one is confronted with the truly neurasthenic woman and one is compelled to use all one's tact and knowledge to prevent a transition into the further alienistic states of "phobias," melancholia, hysteria, hypochondria—in short, some type of actual or borderland insanity.

1. The Mucous Channels and the Blood Stream as Alternative Routes of Infection. C. J. Bond.
2. The Genital Functions of the Ductless Glands in the Female. W. Blair Bell.

3. The Esthetics of Medicine. C. J. Macalister.
4. Henoch's Purpura with Intussusception; Laparotomy; Recovery. S. Barling.

1. **Mucous Channels and the Blood Stream as Alternative Routes of Infection.**—C. J. Bond has shown that small particles of an inert substance like indigo, which is insoluble in the bodily secretions, may under certain circumstances be carried along mucous canals and gland ducts in a direction opposite to that taken by the normal secretion. If non-motile particles of indigo can travel in this manner along mucous surfaces, then it is reasonable to suppose that the organisms of disease can also be transported from the mucous orifices of the body up the intestinal canal and urinary canals to the recesses of organs like the kidney and gall-bladder. Three conditions are necessary for this transportation of foreign particles in a direction opposite to that of the flow of secretion. (1) There must be a reversed mucous current along the channel. (2) There must be some stasis of the normal secretion or excretion in the duct. (3) Or a fistulous communication must exist at the proximal end of the canal by which the contents can reach the surface of the body without passing down the duct. The existence of mucous current so accounts for the carriage of foreign bodies and organisms upward along the bowel. Thus may be explained the close association between appendicitis and duodenal ulceration. There are grounds for thinking that if the condition of the whole intestinal tract were fully investigated in cases of gallstones and gall-bladder disease, not only would appendicular and ileocolic complications be found in many cases, but in some the whole lining mucous membrane would show signs of widespread catarrh of infective origin. There are presented by the author reasons for thinking that, when an organism like the *Bacillus coli* reaches the pelvis of the kidney by ascending the urinary tract, it produces symptoms and effects which differ from those produced by the same organism when it reaches the kidney by way of the blood stream. It is suggested that these differences depend on the fact that the organism is undergoing adaptation to a mucous and urinary environment in the one case and a blood or lymphatic stream environment in the other.

2. **Genital Function of Ductless Glands in the Female.**—W. Blair Bell describes the influence of the ovaries on the uterus, on the general metabolism, and on the rest of the principal organs of internal secretion. With regard to the influence of the ovary on the uterus, it is noted that to some extent the implantation of the fertilized ovum is assisted, possibly by the secretion of the corpus luteum. Further, the activity of the uterus is maintained and regular contractions are promoted, probably by the secretion of the interstitial cells. In the general metabolism the total ovarian secretion appears to promote the excretion of calcium and the retention of phosphorus. And lastly, total ovarian insufficiency arouses increased activity in all the remaining ductless glands.

3. **Esthetics of Medicine.**—C. J. Macalister directs attention to the fact that beauty is a corollary of health, and just as the wiping out of smallpox has done so much to preserve the beauty of the race, in like manner attention to the treatment of those diseases which tend to promote permanent organic changes and deformities and cripplings, added to appropriate measures taken for their prevention, will do much to further the esthetic aspect of the work of the medical man.

4. **Henoch's Purpura with Intussusception.**—S. Barling in reporting a case illustrating this association, alludes to the difficulty of making a differential diagnosis between the two conditions. In intussusception during the first twenty-four hours the belly wall is commonly flaccid, mobile, and not tender in the intervals between the attacks of pain, becoming hard and fixed when the child writhes under an attack of colic. In Henoch's purpura the condition of the abdominal wall often presents exactly similar features; not infrequently, however, the belly is distended, tender, or rigid from the onset of the illness, a condition almost unknown in intussusception. Among the local signs of intussusception the presence of the characteristic sausage-shaped tumor, lying usually on the arc of a circle with its center at the umbilicus, can generally be found. Cases in which an intussusception is suspected, but in which no tumor is felt, should always be examined under anesthesia in which case not more than one in twenty will fail to exhibit the typical tumor. A tumor may be present in Henoch's purpura, being caused by hemorrhage into the mesentery, a coagulum lying in the lumen of the bowel, or a massive interstitial hemorrhage into the bowel wall; and though such tumors will usually lack the characteristic shape and feel of an intussusception tumor, yet it is evident that occasionally the similarity may be so great as to lead to laparotomy being performed. To sum up: When purpuric manifestations in the skin or joints are absent, the most important points in making a differential diagnosis between the two conditions are a reliable history, a careful examination of the urine, and the presence or absence of the characteristic lump in the abdomen when examined, if necessary, under anesthesia.

*March 24, 1913.*

**Stasis Reaction in Arteriosclerosis.**—Hertzell believes that he has discovered a reaction of diagnostic value in arteriosclerosis. If with the patient in repose the blood circulation in both legs and one arm is interrupted, there results a moderate increase of blood pressure in the free arm. But while in normal subjects this increase averages only about 5 mm. Hg., in arteriosclerotics it may amount to as much as 60 mm. and even more. This phenomenon naturally explains itself as follows: Arteriosclerotic blood vessels have lost to a greater or less extent their native property of compensating for vascular disturbances. When more blood is forced into the vessels of a given area these no longer yield, and being rigid the tension must rise. The fact that this rise may vary notably with the case may be utilized to determine the actual amount of vascular damage. A small rise would indicate a certain amount of localized arteriosclerosis, and a maximum rise would indicate total arteriosclerosis. It should also be possible to determine the seat of a localized arteriosclerosis. The positive result of this test furnishes an earnest indication of treatment to prevent if possible the extension of the process. Hydrotherapeutic resources which are indicated only when the power of vascular compensation is retained are naturally contraindicated in patients who react positively.

**Athletics and Stimulants.**—Hueppe concludes his interesting comments on this subject. In reference to the demand in physical exertion for quickly oxidizable carbohydrates, he states that but for collateral ill effects alcohol would be superior to all forms of the latter. It exerts both a toxic and narcotic effect. It can therefore be used only for a brief period. Its stimulating action is real, and not merely a narcotizing action upon the nerves which feel the exhaustion of exercise. Alcohol is naturally not adapted to training, for as a stimulant it antagonizes the aim of the latter to economize vital force. The place of alcohol in athletics is only when a stimulant is really needed, and this can only be during the actual contest. There is a practical distinction between alcohol *per se* and alcoholized drinks, for beer and wine contain much nutritive material outside of their alcohol content. Japanese wrestlers, like those of classic European days, are overnourished by combinations of fattening food and wine.

These facts illustrate the teaching sometimes heard that gluttons are saved from their excesses by drinking, and hard drinkers from alcoholism by overeating. The author likewise revives another old dogma that a man gone stale from overtraining may be restored to equilibrium by drinking plenty of strong beer for a short time. When alcohol acts as a muscle stimulant its effects are first noticeable in groups of muscles of no special importance in athletics. Scheffer's experiments on himself appear to show that alcohol first increases, then diminishes the excitability of the nervous system, including the nerve centers, paths, and terminal muscle filaments. The prescription of alcohol to soldiers under certain conditions is no new thing. Even the mythical Odin permitted drink only when a march was finished. This censorship on the use of alcohol was, however, due largely to its demoralizing effects on discipline, including the treatment of civilians, and the conquered and subject peoples. Heroes, like Odin and Hector, were afraid to drink before a battle.

*March 25, 1913.*

**Is Beriberi Endemic in Europe?**—Schüffner discusses this interesting question, interesting of course to Americans as well, at much length. In 1897 he began the study of the disease in Sumatra, where it prevailed epidemically with high mortality. In Europe such a disease could not escape observation in epidemic incidence. In Sumatra, however, the disease occurs at present in sporadic form only, and it is of course conceivable that it might thus occur in the culture lands where sanitation may be trusted to hold it in check. All the data obtained during recent years point to an alimentary origin for this affection, which would also favor the appearance of the latter as an exotic, in accordance with the modern tendency of disease in general to become universal in some degree. Beriberi differs but slightly from our polyneuritis. Typhoid and dysentery patients in Sumatra, once nourished very largely with rice, developed beriberi with shocking regularity. This no longer occurs under a changed diet. The important task at present is to study European polyneuritis with especial reference to an alimentary origin, and to cumulative cases. Conolly and Norman have described petty epidemics of polyneuritis in Irish insane asylums. Thus in 1894 out of 1503 inmates 174 developed the disease and 25 of these died. A similar episode occurred in France in 1898 (Chantemesse and Raymond) while even in the United States one was reported in 1896 by Bondurant of the State Insane Hospital, Alabama. No rice was used at Dublin and information on this point is defective in the other episodes. Of ordinary or secondary polyneuritis in Europe, numerous cases follow typhoid and other acute infectious diseases and are commonly ascribed to the bacterial toxins. These may be brought into relationship in part with an alimentary origin, as may also the polyneuritis of pregnancy and alcoholism. The author believes that beriberi may sometimes occur with the clinical picture of Landry's paralysis. He claims no originality in his thesis, for Oppenheim and others have speculated in a like manner on the existence of European beriberi.

**Successful Treatment of a Recurring Sarcoma of the Ovary.**—Seeligmann extirpated a sarcoma which extended from the lesser pelvis (which it filled) to the vault of the diaphragm. Compressing the spine it had caused a slight gibbosity. When the author first prepared to operate, because of the extremely forlorn state of the patient—to whom slight relief would have meant much—the outlook after preliminary laparotomy was so poor that he closed the external wound. Morphine alone gave some relief for the next week, after which a sudden improvement in the general state led the author to further attempts in the direction of prolonging life. From precedent arsenical remedies were first thought of and one of the newer synthetics was injected intravenously. The Röntgen rays were exhibited at the same time. The results of the combined treatment were astonishing. The growth slowly dwindled in size, and the general condition improved at the same time. An *x*-ray photograph showed that metastases had actually occurred in the last dorsal and first lumbar vertebræ, although the treatment had seemingly arrested their progress. Eight weeks after the inauguration of the treatment the patient was shown to the Hamburger Aertzliche Verein as practically well. The author, while admitting that equally desperate cases of sarcoma may have been cured in various ways, advocates the use of the same measures in all inoperable cases not only of sarcoma but of carcinoma as well.

### Deutsche medizinische Wochenschrift

*March 20, 1913.*

**Parasyphilis.**—Schoenborn and Cuntz discuss the question of what manifestations should receive this title. Fournier's definition, never unanimously acceptable to practitioners, is no longer tenable. This authority would use the term for any condition closely paralleling syphilitic manifestations even in case of occurrence in nonsyphilitic soil. The negative criteria comprised refusal to heal under mercury and iodine. We now, of course, exclude syphilis by biologic tests; and refusal to heal under certain remedies no longer possesses the old significance. Baginsky, writing of infantile syphilis, would do away with the term parasyphilis, and this advice also holds good for all ages. Moreover, the word is superfluous from any viewpoint. The more recent attempt to limit parasyphilis to tabes and paralysis on the ground that these affections are due to impregnation with antibodies is uncalled for; as Danlos states, the original syphilis is still present in these affections. The authors believe that the time is not far distant when these two neuroses will simply be spoken of as syphilitic outright. The authors conclude by appending a striking corroboration of his thesis which reached him after his article had gone in type. This was Noguchi's photograms of spirochetes in the neighborhood of the cortex in general paresis. This find should clinch the matter.

**Cholesterin Content of Blood in Disease.**—Bacmeister and Henes have shown that this content is diminished by cholesterin-poor diet, age, emaciation, poor general condition, and especially in all fevers. The content is increased in cholesterin-rich diet, in all severe anomalies of metabolism—diabetes, obesity, nephritis—and arteriosclerosis. In convalescence from typhoid we see an increased content develop which persists for months. This cannot be said of convalescence from other severe fevers, hence its rationale is obscure. It is probable that all cholesterin in the body is exogenous and it is certain that it is not a product of nerve catabolism. The fluctuations in blood content depend in some manner on the behavior of the cholesterin in the tissue cells.

**The Adrenals and Fat Metabolism.**—According to Landau the cortex of the adrenal shows an increase in the total content of lipoids under the most varied conditions, which have in common one of two features—lipoid retention or increased lipoid formation. There is a corresponding condition characterized by poverty of the cortex in lipoids. The variations of this organ in lipoid content result from primary changes in the same content in other organs. They appear to play no part in the nutritional state of the body. The function of the adrenal cortex is not in any way bound up with the genesis of lipoids, but with the medullary portion and sympathetic.

## Insurance Medicine.

**Methods of Uranalysis Applicable to Insurance Examinations.**—Stephen H. Baxter says that while the average practitioner who is also doing insurance work may not be able to carry out the numerous investigations of gastric juice, of the blood, of various exudates, etc., in the urine he finds an easily obtainable secretion which can be accurately tested by means of rather simple methods. The importance of such examination cannot be overestimated, for diseases of the kidney, affections of the cardiovascular system, diseases of metabolism, and chronic and acute suppurations may all be reflected in the urine. The cursory physical examination for insurance frequently does not amount to much, because of the lack of time and the unwillingness of the applicants to undress, etc. The personal history of the applicant may be not only untrue but also misleading. Often then the only objective findings are those obtainable from the examination of the urine.

Yet such an examination is frequently made in a manner that renders it useless. Thus of 119 cases of albuminuria as detected in the home office of Baxter's company, the condition was diagnosed by the local examiners in only 41, or in 34½ per cent. In five cases it was reported present but was not found at the home office. Most of the cases showed casts, etc., and thus were very important from the standpoint of proper selection. Baxter's company has adopted some standard tests for examination of the urine and these he gives in some detail. For preserving specimens in transit, boric acid is recommended, for it does not interfere with the tests. It is used in the proportion of 2½ grains per ounce, a tablet of this weight being put into the specimen bottle when it is sent out. Such tablets must be specially made, for those from the druggists usually contain starch. The specimen is always filtered. There is nothing gained by attempts to get rid of very small amounts of turbidity by using infusorial earth, talcum, etc., for these methods lead to the loss of the small amount of albumin as well; large amounts can be detected in the presence of some turbidity. The heat test is the one of choice, because of reliability and simplicity. Ulrich's technique is best. The reagent used is a saturated solution of common salt, acidified with 1 per cent. acetic acid. A few c.c. are poured into a test tube and boiled. The urine is then allowed to flow over the hot acid brine from a pipette, forming a sharp line of contrast. The hot brine will coagulate the albumin, while the acid will prevent the precipitation of the phosphates. The presence of salt prevents the precipitation of "nucleo-albumin." Practically, the phosphates are sometimes precipitated by this method, and it is best to add to the urine as a routine measure about one-sixth volume of the acid salt solution before applying the test. Albumose is the next important substance. Its presence may be detected by repeating the test just described without heating the salt solution. If albumose is present, a ring will form at the point of contact as before. Proper light is of great importance. On a bright day diffused sunlight is inferior to direct, and on cloudy days artificial light must be employed. A laryngoscope lamp with condenser gives the best light. The Heller test with cold nitric acid is not as satisfactory as the above technique.

Glucose is the next important pathological constituent. In doing the familiar tests for sugar, albumin must be removed if present in more than mere traces. Ingestion of chloral hydrate, chloroform, morphine, camphor, and other drugs of that group may be followed by a positive and therefore misleading reaction; sometimes the same takes place after the use of salicylic acid, sulphonal, benzoic acid, salol, santonin, copaiba, and acetphenetidine.

Such sources of error may sometimes be eliminated by diluting the urine. If but a small amount of sugar is supposed to be present, only a small amount of copper must be used; otherwise the reaction is not typical. If the reaction is at all ambiguous the fermentation test should be considered the court of final appeal, for no substance found in the urine except sugar is fermentable by yeast with the production of carbonic acid. The sugars that ferment, too, are those found in true diabetes. Thus pentosuria and lactosuria are excluded. The fermentation test should be controlled by adding the yeast to a normal urine, to see how much to allow for any sugar in the yeast, and to a specimen of sugar in solution to prove that the yeast is active. The phenylhydrazin test and the polariscopic tests are not applicable to insurance in the great majority of cases. Microscopic examination of the sediment is of great value, but is usually done at the home office. Such examination usually tells whether the albuminuria is of grave or of little import.—Second Annual Meeting of the Medical Section of the American Life Convention, Sept. 3, 1912.

**Points to Insure Honesty in Insurance Examinations.**—That insurance fraud is not, ordinarily, very frequently practised, is the opinion of Dr. Lister, in addressing the Life Assurance Medical Officers' Association, in London, on May 1, 1912. To be successful, fraud necessitates what amounts to a conspiracy on the part of the applicant, possibly an inspector of agents, a doctor, or a lawyer, and a couple of friends. A collusion of this size can rarely be carried through. Lister disapproves of the examination for insurance by the proposer's own medical attendant, and cites a case where a Lady Bountiful of a district, apparently finding it inconvenient to go to London for her examination, asked permission of the Head Office to allow her local medical attendant to do it. This was granted; the woman was passed, and eighteen months later, she died with uterine cancer, proving a heavy loss to the company. No knowledge could be obtained as to whether the local attendant was in the secret or not; or whether the applicant herself had a knowledge of her condition. Fraud sometimes lies in intent, rather than in actual commission. The local medical attendant makes a better medical referee than examiner, often elucidating facts not clearly brought out by the applicant himself. Some diseases, looked upon in the past with decided severity by insurance companies, would have to be regarded in a broader and much more lenient light in the future. Phthisis, for instance, is one, the prognosis of which is steadily improving as a social disease; and the companies are dealing with masses and classes, and not individuals. This is not meant for an excuse to gloss over serious symptoms, known to be of much importance by the examiner. The question of drugs is a vital one, for it often helps in clearing up an otherwise doubtful case. An uncertain sugar reaction has been explained and cleared up by the applicant himself announcing, after having been questioned, that he was taking codeine pills.

# Book Reviews.

The Practice of Urology, a Surgical Treatise on Genitourinary Diseases, Including Syphilis. By Charles H. Chetwood, M.D., LL.D., Professor of Genitourinary Surgery, New York Polyclinic; Visiting Genitourinary Surgeon to Bellevue Hospital; Special Consulting Surgeon to J. Hood Wright Hospital, St. John's Hospital (L. I. City), Nassau Hospital (Mineola), White Plains Hospital; Member American Association of Genitourinary Surgeons; American Urological Association; L'Association Internationale d'Urologie, etc. Price $5.00. New York: William Wood and Company, 1913.

The latest of a series of good books on any special department of medicine unquestionably profits by the omissions and errors of its predecessors. The author, however, bears a compensatory responsibility of presenting the new facts and theories as well as the discarding of obsolete and impractical procedures. This work fully meets all of these conditions. It contains 42 chapters covering more than eight hundred large octavo pages. Within this comparatively small space every urological topic is discussed and sufficient attention is accorded to those of importance. It is not possible to praise one section more than another, since the book is so well balanced that it is uniform in excellence. The author directs special attention to the modernity of those chapters on the local treatment of gonorrhea, the application of serum diagnosis and serum therapy, advancement in cystoscopic and functional renal diagnosis, various features in surgical technique, and the latest on salvarsan therapy. The advice on post-operative treatment merits praise, since it contains many instructions and suggestions of great value to less experienced operators. Dr. Chetwood is one of the few authors who admit the possibility of diagnosis of certain genitourinary diseases by differentiation of epithelia in the urine sediment. Unfortunately he has omitted the scale of enlargement in the plates selected which materially decreases their teaching value. On page 24 appears the description and illustration of Guyon's mandarins (illy termed "catheter directors") for soft or semisolid catheters, but the most useful curve for the relief of total retention from prostatic hypertrophy, that of a semicircle, is not mentioned. On page 122 Luys' segregator is described and illustrated, yet Cathelin's, which is so totally different in principle that it possesses its own field, is omitted. Dr. Chetwood does not accord full credit to his confrères for their contemporary conception and introduction of mechanical devices, notably the modern urethroscope. The closing chapter on syphilis is very condensed, so much so that it reads like a task of duty rather than one of pleasure. It nevertheless contains a wealth of information. His technique of the intravenous injection of salvarsan is simpler but more dangerous than that of Assmy, who safeguards against abscess by allowing the salt solution to flow into the vein both before and after the salvarsan solution. Those who expect a urological encyclopedia in one volume will be disappointed, but readers who are content with crisp, authoritive information covering the wide field of urology will welcome this work. The literary style is that of an experienced writer and appeals through the delightful scarcity of personal pronouns.

Cardiovascular Diseases: Recent Advances in Their Anatomy, Physiology, Pathology, Diagnosis, and Treatment. By Thomas E. Satterthwaite, A.B., M.D., LL.D., Sc.D.; Consulting Physician Post-Graduate, Manhattan State, Orthopedic, Babies', Champlain Valley Hospitals and Northeastern Dispensary; Member American Therapeutic, State and County Medical Societies, American Medical and Greater New York Medical Associations, New York Academy of Medicine, Harvey Society; Life Member New York Pathological Society; Honorary Member Washington (D. C.) Medical and Surgical Society; First Lieutenant Medical Reserve Corps, U. S. A. Price, $3.00. New York Lemcke and Buechner, 1913.

This work, fully described in the sub-title, presents in attractive form the results of the labor of many diligent and capable men. Among the anatomists, Keith, Flack, Tawara; of the physiologists, Gaskell, Einthoven, Lewis, Cushny, and from the clinicans, Mackenzie, Hering, Janowski, and not omitting the author, should be cited as having made substantial contributions to the better understanding of a class of diseases second only to tuberculosis in their fatality. The results of laboratory and clinical observations of this last decade have been recorded in numerous journals; here we find all that is of importance presented in attractive form, so that this book is a fitting supplement to the "Diseases of the Heart and Aorta" published by the author in 1905. The value of the volume is enhanced by the large number of illustrations of instruments and tracings produced by them, and their use is fully explained. Although much doubt as to the interpretation of graphic pulse tracings must exist until the normal is sharply defined and the abnormal classified, yet for permanency and comparative study these methods constitute a real advance and will likely lead to more accurate knowledge. Of the chapters which appeal more strongly to the physician, those on the high frequency currents in arteriosclerosis, uses of carbon dioxide, and the cardiovascular thromboses are unusually helpful. The mobility and malpositions of the heart can nowhere else be found so succinctly presented as here. With the author's practical classification of the arrhythmias, myocardial diseases, and malignant endocarditis, not only the clearing up of our knowledge but distinct advance in the management of these conditions has been accomplished. From the study of this work not only the general physician but as well those working in the narrower field will acquire valuable information, critically presented by a brilliant exponent of diagnosis and treatment.

Surgical Operations with Local Anesthesia. By Arthur E. Hertzler, M.D., Surgeon to the Halstead Hospital, Halstead, Kan., and to the Swedish Hospital, Kansas City, Mo. Illustrated. Price, $2.00. New York: Surgery Publishing Company, 1912.

The object in presenting this book to the profession is to furnish in a convenient form the technique of some of the commoner operations that can be done in a satisfactory manner under local anesthesia. The author has had in mind the needs of the general practitioner and the surgeon who works without the advantages which accessibility to a hospital affords. For this reason, some of the major operations have been omitted which require considerable experience in the use of local anesthetics. The book is unusually well illustrated.

Outlines of Psychiatry. By William A. White, M.D., author of "Mental Mechanisms," Superintendent Government Hospital for the Insane, Washington, D. C.; First Lieutenant, Medical Reserve Corps, United States Army; Professor of Nervous and Mental Diseases, Georgetown University, Washington, D. C.; Professor of Nervous and Mental Diseases, George Washington University, Washington, D. C.; and Lecturer on Insanity, U. S. Army and U. S. Navy Medical Schools. Fourth Edition. Revised and Enlarged. Price, $3.00. New York: The Journal of Nervous and Mental Disease Publishing Company, 1913.

It is not necessary to add anything to the favorable opinions which the previous editions of this work have evoked in these columns. The present edition contains thirty-six more pages than the last, the additional matter being found in the chapters devoted to the description of the psychoses, and consisting also of the chapter describing the Binet-Simon scale for measuring intelligence. One excellent feature of the present edition is the inclusion of extracts from case histories. This greatly enhances the value of the book from the didactic viewpoint. The chapter on general symptomatology may be cited as an example of the author's clear exposition of the subject matter and of his thorough presentation of the latest concepts in psychopathology. Among the topics discussed in this chapter are clouding of consciousness, dream states, disorientation, flight of ideas, Ganser's symptom, and the complex. The Binet-Simon tests are given in full. The entire work represents an admirable exposition of modern psychiatry.

Minor Surgery. By Leonard A. Bidwell, F.R.C.S., Senior Surgeon to the West London Hospital, Dean of the Post-Graduate College, Consulting Surgeon to the Blackheath and Charlton Hospital and to the City Dispensary. Author of "Handbook of Intestinal Surgery." Second Edition, Revised and Enlarged. With one hundred and twenty-nine illustrations. Price, $3.75. London: University of London Press, Hodder and Stoughton, and Henry Frowde, 1913.

This book makes no pretence to be a complete treatise on surgery, but it gives clear directions for the management of everyday surgical work. It should prove of use to the practitioner who has mainly office work and minor surgery to attend to. A feature of the volume is that very few alternative methods are given; the author selects what he believes to be the best, and the reader is saved the difficult task of making a choice. The book is authoritative, and is based upon the personal experience of the author, and it is well printed and contains a sufficient number of serviceable illustrations.

Guide to Midwifery. By David Berry Hart, M.D., F.R.C.P.E. Lecturer on Midwifery, School of the Royal Colleges, Edinburgh. Formerly Obstetric Physician, Royal Maternity and Simpon Memorial Hospital, Edinburgh. Formerly Gynecologist to the Royal Infirmary, Edinburgh. Consulting Gynecologist, Leith Hospital. Sometime Examiner in Midwifery and Gynecology in the Universities of Edinburgh, Oxford, Liverpool, Birmingham, and to the Royal College of Physicians, Edinburgh. Honorary Fellow of the American Gynecological Society. Honorary Fellow of the Berlin Obstetrical Society. Corresponding Fellow of the Leipzig Obstetrical Society. Honorary Librarian to the Royal College of Physicians, Edinburgh. With four Illustrations in color and two hundred and sixty-eight diagrams. Price, $6.00. New York: Rebman Company, 1913.

This new book on obstetrics is distinguished by an individuality and independence of observation which are characteristic of the author, and which are not often met with in medical textbooks of the present day. The work is divided into two parts. The first part deals succinctly with the subject of obstetrics in general; and to the several chapters there have been added instructions as to what should be done, and what specimens should be examined in order that the student may thoroughly understand what he has been reading about. The second part consists of lengthy notes on various subjects, which are not absolutely essential, but which certainly add to the interest of the scholarly student. There is in this part a chapter on Evolution in Obstetrics, with an explanation of Mendel's experiments and a discussion on Mutation and Variation. Another section is on Internal Secreting Glands in relation to Obstetrics. The author has exercised a commendable restraint in the matter of illustrations. The volume is sufficiently illustrated, but it is not over illustrated; and certainly no one would buy the book for the sake of the illustrations alone. The text is the important part, and it is admirable. There is a bibliography of about twenty pages which, while not complete, cannot fail to be of great value. Here, as well as throughout the volume, the author makes reference to all that is worth while in the literature of the subject; and American authors and publications receive their due recognition, a feature not always noticeable in transatlantic books. This volume is stimulating, and should prove of interest to teachers as well as to students and practitioners.

General Chemistry of the Enzymes. By Hans Euler, Professor of Chemistry in the University of Stockholm. Translated from the revised and enlarged German edition by Thomas H. Pope. First Edition. First thousand. Price, $3.00. New York: John Wiley & Sons, 1912.

The present volume is founded on two reports which were contributed to the *Ergebnisse der Physiologie* for 1907 and 1910, but the original German edition has been considerably enlarged and rewritten, and it is from this that Mr. Pope has prepared his translation. The subject is one of the most highly technical with which investigators are dealing, and the book therefore does not lend itself to review in brief, but it may be said that while primarily intended for the purposes of the research worker it also contains much information of directly practical value to the medical profession. This is particularly the case in regard to the sections dealing with the behavior of the digestive ferments and the methods for estimating them quantitatively in stomach contents and stools. The list of chapter headings includes the special chemistry of the enzymes; physical properties of the enzymes; activators, paralyzers, and poisons; chemical dynamics of enzyme reactions; influence of temperature and radiation on enzymic reactions; chemical statics in enzyme reactions; enzymic syntheses; specificity of enzyme action. The closing chapter contains working directions for carrying out many of the methods required in the study of the enzymes as well as tables for determining the commoner sugars by Bertrand's method. The book is the latest and fullest on the subject and is therefore essential to all those interested. A special word of congratulation is due the translator for the success with which he has carried out what must have been a task of more than usual difficulty.

The Mechanistic Conception of Life. Biological Essays by Jacques Loeb, M.D., Ph.D., Sc.D. Member of the Rockefeller Institute for Medical Research. The University of Chicago Press, 1912.

Dr. Loeb has collected in this volume several essays written on different occasions, but all characterized by the general tendency "to analyze life from a purely physicochemical viewpoint." These essays deal with the well-known work of the author in artificial fertilization of the lower orders of animals, in the study of the rôle of environment upon morphological structure and behavior of animals, and in the discoveries of the important rôle of salts in the preservation of life of simple animal forms, and, by inference, of the simple cells composing higher organisms. Dr. Loeb is frankly a materialist and thinks that the contents of life, "the wishes and hopes, efforts and struggles, and unfortunately also disappointments and suffering" are amenable to physicochemical analysis. He points out how numerous apparently "psychic" phenomena of lower life have been traced to the effects of physicochemical influences and sees no reason why such explanation will not be finally found for more complex actions of higher organisms. His own work on the subject is probably the most significant, and the volume before us, therefore, forms an important landmark. The brief sketch of its subject given above should attract numerous readers among medical men.

New Aspects of Diabetes. Pathology and Treatment. By Prof. Dr. Carl von Noorden, Professor of the First Medical Clinic, Vienna. Lectures Delivered at the New York Post-Graduate Medical School, New York. Price, $1.50. New York: E. B. Treat & Company, 1912.

Dr. von Noorden has added another small monograph to his interesting and valuable series published in English by Treat & Company. The present number is amplification of his presentation of diabetes, as first discussed in a monograph entitled "Diabetes Mellitus." It consists of four chapters, headed respectively "The Source of Sugar," "The Rise in Caloric Production and Its Causes," "The Control of Sugar Formation and Its Disturbances: Theory of Diabetes," and finally "The Therapy of Diabetes." An additional article is devoted to acetonuria. The booklet supplies much that is instructive, illustrative cases being given from Dr. von Noorden's extensive experience with the disease in question. Numerous practical hints on therapy are scattered through the text, those on the interpretation and treatment of acetonuria being especially valuable. The monograph is to be strongly recommended to the internists.

Golden Rules of Surgery. Especially Intended for Students, General Practitioners, and Beginners in Surgery. By Augustus Charles Bernays, A.M., M.D., Hdlbg., M.C.R.S., Eng. Life member of the German Society for Surgeons of Berlin, Chief Surgeon Lutheran Hospital, and for Twenty Years Professor of Anatomy and Surgery in St. Louis, Mo. Second Edition Revised and Rewritten by William Thomas Coughlin, M.D., Assistant Professor of Surgery, Chief of Clinic, St. Louis University Medical School, St. Louis, Mo. Price $2.25 net. St. Louis: C. V. Mosby Company, 1913.

The entire absorption of the first edition made it necessary to issue the present one. Its enlargement and elaboration by the junior author has made it possible to cover the entire field of surgery in a thorough and systematic manner, at the same time preserving the character and charming style that made the first edition of this book popular. In the appendix are to be found the rules in force in the author's service at St. Louis University (Rebekah) Hospital, which pertain to preoperative treatment (general and regional) and postoperative treatment; also rules for dressing patients and the keeping of records.

This little volume will bear reading and re-reading as it well sets forth the fundamental truths of surgery and gives a bird's eye view of the science and art of surgery.

A Practical Manual of Venereal and Generative Diseases, Spermatorrhœa, Impotence, and Sterility in Both Sexes. By Gerald Dalton, Late Assistant Surgeon St. Francis' Hospital and Lecturer to Nursing Staff; Assistant to Skin Department, Charing Cross Hospital; Lecturer on Ambulance, London County Council; Member British Medical Association; Member W.L. Medico-Chir. Society; Hon. Sec. Assoc. Physicians and Surgeons. Author of "Gleet and Chronic Diseases of Prostate;" "Modern Treatment of Gonorrhœa;" "The Aix La Chapelle Treatment of Syphilis," etc. Price 4s. net. London: Henry Kimpton, 1913.

In compiling this little work of 156 pages it is the author's primary intention to bring, in a practical and concise form, the more modern forms of treatment of a most important branch of medical science which unfortunately receives too little attention and study. He points out that the importance of a rational and scientific basis for treatment of these common, but painful and often most intractable maladies, cannot be overestimated.

# Society Reports.

## MEDICAL SOCIETY OF THE MISSOURI VALLEY.

*Twenty-fifth Semi-Annual Meeting, Held at Kansas City, Missouri, March 20 and 21, 1913.*

THE SECOND VICE-PRESIDENT, DR. B. T. QUIGLEY, MOUND CITY, MISSOURI, IN THE CHAIR.

**Genital Tuberculosis in the Female.**—Dr. W. O. HENRY of Omaha stated that abortions, gonorrhea, and other inflammations, as well as all injuries or contusions and a general rundown or anemic condition might be predisposing factors in the origin and development of genital and peritoneal tuberculosis. We should be more careful and thorough in examinations of cases lest we overlook the true conditions, at the time when they were most amenable to treatment. Our present-day duty and privilege of helping to prevent and cure these cases, as contrasted with those of our predecessors, were so great that it behooved us to wisely safeguard the public by teaching prevention and encouraging the afflicted by a favorable prognosis, unless other serious complications were also found.

**Management of Genital Tuberculosis in the Female.**—Dr. PALMER FINDLEY of Omaha pointed out that genital tuberculosis in woman was rarely a direct cause of death. The fatal issue was usually determined by a primary lesion in the lung or bowel. In at least fifty per cent. of cases there were some symptoms directly chargeable to the tuberculous lesion in the genital organs. It follows that in fully half the cases there was no urgent indication for operative interference. Inasmuch as genital tuberculosis was rarely primary we must discriminate, if we could, between the symptoms directly due to the primary lesion and those due to the secondary lesion in the genital organs. The symptoms referred to the genital organs would usually yield to palliative measures. A radical operation was rarely justified for relief from symptoms caused by genital tuberculosis. There was danger in operative interference from the awakening of a latent primary focus, from the high primary mortality in these cases and from the possible unnecessary sacrifice of organs, inasmuch as spontaneous healing was a possibility as in tuberculosis elsewhere in the body. In tuberculous peritonitis the cause of death in 90 per cent. of cases was chargeable to the primary focus. In operating for tuberculous peritonitis it was well to remove the tubes when infected, in order to cut off the source of supply to the peritoneum. The utmost conservatism should be exercised in dealing with ovaries and uteri in young women. The exudative type of tuberculous peritonitis was alone favorable to operation. One should not operate in the presence of a fever or an active primary focus in the body. Medicinal and hygienic treatment was not to be underrated in the management of these cases. In the absence of severe symptoms directly referred to the lesion in the genitalia or peritoneum operative measures should give way to the usual hygienic measure.

Dr. H. C. CROWELL of Kansas City, Mo., said in a large percentage of cases of tuberculosis of the genital organs the symptoms were very acute and pronounced, so far as his observations went. Whether the disease caused death immediately or not was probably open to question, but ultimately the majority of these cases, even with a local tuberculosis in the pelvis, succumbed, as did patients with other forms of the disease. His experience had been limited to the cases with pelvic manifestations. He had had quite a number of cases in which there was no evident involvement of the lung, and operative procedure had effected a perfect cure, and the patients had recovered without secondary involvement of other organs. He had had other cases of tuberculosis of the kidneys in which he was able to discover tubercular foci outside of the kidney, and later those patients succumbed to a general tuberculosis. Some fifteen years ago a woman, 26 years of age, unmarried, came to him with what appeared to be a pyosalpinx. Examination of the discharge from the uterus did not demonstrate satisfactorily the nature of the infection; but in opening up he found large abscesses and ulceration in the posterior surface of the uterus, and so extensive was the suppurative process that he did a hysterectomy, cleaned out everything thoroughly, and the woman made a perfect recovery.

Dr. HENRY, in closing, said it would be a mistake to leave an active focus of tuberculosis in the pelvis or in any of the pelvic organs and expect by local treatment to get rid of it. Removal of the local focus was essential to the patient getting well.

**The Surgical Colon.**—Dr. A. L. BLESH of Oklahoma City said the surgery of this condition consisted in the restoration or establishing of colonic continuity. This might call for anything in the way of an operation from the simple severing of a constricting band to an ileosigmoidoscopy, sometimes with, sometimes without, resection. It was manifestly impossible to treat these conditions by any rule of thumb procedure. But there were a few fixed features connected with the embryology of the organ that, if borne in mind, would assist materially in guiding the surgeon. 1. The location of the most fixed points in the colonic circle, viz., splenic and hepatic flexures. 2. The termination of the ileum, for the reason that here was found normally the shortest ileal mesentery. 3. The cecum (cecum mobile of Wilms). 4. Diverticula. He desired to emphasize the statement that not all the embryological deviations or reversions of the colon were to be considered surgical by any means. Indeed, even where we were groping our way surgically we could not as yet be dogmatic.

**The Rôle of Tonus in the Digestive Canal.**—Dr. JOHN M. BELL of St. Joseph, Mo., stated that atony of the digestive tract existed in all gradations, from a mere slight delay in motility to absolute kinking and retention; it was, therefore, impossible to outline a procedure to restore all cases. The keynote of treatment, except in those cases of more or less acute kinking, was the restoration of normal tone, not merely to the digestive canal but to the body, and came within the domain of medical treatment, not essentially drugging, but rather hygiene, diet, daily habits, and all those measures which tended to restore vitality.

**Diverticulitis of the Sigmoid.**—Dr. ARTHUR D. DUNN of Omaha, after considering the etiology, pathology and reporting five cases of diverticulitis of the sigmoid, emphasized the following symptoms, which, in the absence of evidence to the contrary, were presumptive of a diverticulitis: 1. Alternating constipation and looseness of the bowels in an individual not previously much troubled in this respect, and which were accompanied by fullness, soreness or colicky pain in the hypogastrium. 2. Febrile manifestations and a sharp neutrophilic leucocytosis. 3. Frequency of and pain on urination in the presence of symptoms referable to the lower colon. 4. A palpable tumor mass, usually discovered by rectal examination, often sausage-shaped and extending to the left in close relationship to the sigmoid.

**Membranous Pericolitis.**—Dr. CHARLES RYAN of Des Moines related his personal experience, which had been confined to 12 cases within the past eighteen months, none of which would furnish especial interest for a detailed description except one. This case was a woman, 38 years of age, who presented symptoms of chronic cholecystitis and chronic appendicitis, which was his diagnosis. At operation there was found a well-developed membrane extending from a point about three inches above the caput coli to a point on the transverse colon two inches to the left of the median line; the transverse colon had been raised until it occupied a position approximating the anterior border of the liver, the gall-bladder being covered, and the membrane spreading over the anterior surface of the stomach. The appendix was kinked, the distal end being incarcerated in a well-formed Lane's kink. Simple division of this extensive membrane and Lane's kink, with the application of sterile vaselin to the latter, with appendectomy and cholecystotomy was the treatment. While she was greatly benefited the symptoms did not entirely disappear. The results in 12 cases at the present time were: Completely cured, 4; greatly benefited, 3; showing recurrence to a variable degree, 3, and 2 cases operated within the past week.

Dr. HERMAN E. PEARSE of Kansas City, Mo., emphasized the importance of diagnosis, and then discussed the choice of operative procedures in cases of malformations or deviations of the colon.

Dr. C. C. CONOVER of Kansas City, Mo., recalled the case of a woman who had stenosis three inches to the left of the hepatic flexure, with alternating constipation and diarrhea. She had been treated for neurasthenia for almost four years. She had symptoms of intestinal stenosis. Her case having been diagnosed, the band or pericolic membrane was removed, she recovered, and gained twenty-five pounds in weight.

Dr. HENRY S. MUNRO of Omaha had noticed one thing in common with every method of treatment in the class of cases under discussion, and that was a carefully regulated dietetic regimen, coupled with systematic exercise, must follow the operative procedure, no matter what it was.

Dr. E. W. POWELL of Omaha said that if we could get these cases to the internist early he could make the diag-

nosis and correct the condition before the patient got to the stage of the pathological condition known as Lane's kink, but unfortunately the average patient did not consult the internist or the surgeon early. He went on and lived the way he wanted to until he got into trouble, and then he consulted, first, the interest, who was unable to cure him; he tried every other thing, among them osteopathy, after which the physician got a crack at him and some method was devised of breaking up the band or Lane's kink, whatever it might be. Personally, he thought the simplest operation that would correct the deformity was the one that was ideal.

Dr. JOHN F. BINNIE of Kansas City, Mo., said there were colons of all sorts and peculiar shapes tucked away in all sorts of ridiculous fashions, and yet they worked very well. If there was a mobile cecum and a mobile (lowest) portion of the ileum, we had a loop of intestine which was pretty much in the same condition as the normal sigmoid, and the intestinal work could be carried on very well in that individual; but if we had a fixed ileum near the cecum, and a mobile cecum, then, of course, the cecum could pop around in various directions and produce temporary obstructions. In operating he did not bother about ileal kinks and mobile cecums very much unless he found them combined. In operative work, or in post-mortem work, when he had exposed the cecum and found it mobile, he had looked at the sigmoid and found it plastered down to the abdominal parietes. That, he thought, was usually the case. Whether it was a congenital condition or not, he did not know, but he thought many of these conditions were congenital.

Dr. WILLIAM T. REYNOLDS of Kansas City, Mo., stated that in May last a girl, 14 years of age, had trouble in the right side. He operated on her with the idea that he had to deal with appendicitis. He found the appendix comparatively normal, but there was a membrane at the head of the cecum. There was nothing to be observed in the formation of the membrane upon the colon higher up. After operation she went home and was well for about six weeks. Since then she had been having the same pain as formerly. He operated a second time and found a smooth, white glistening membrane high up on the colon which had formed between May and four weeks ago.

Dr. HOWARD HILL of Kansas City, Mo., said more observation was needed as to what caused these malformations or deviations of the colon. The looseness of attachment of viscera might be responsible primarily for angulation and similar conditions. When a patient had difficulty in propelling the contents of the intestinal tract through to the outer world, if it produced pain and discomfort, that patient would consult a surgeon. There was no use in operating on the cecum alone, as in six or eight weeks these patients got into the same condition they were in before operation. An ileosigmoidoscopy should be done. The difference between an ileosigmoidoscopy and operations upon the cecum and colon was that after an ileosigmoidoscopy the patient got well slowly but remained well.

Dr. M. J. FORD of Omaha cited two cases. In one, on opening the abdomen he found the colon and ascending colon in proper anatomical position, but within an inch and a half of the cecum and caput coli, and extending up over the colon for three inches there was a distinct band running longitudinally across the colon, holding it down. This was released. The other case was a girl, 22 years of age, who had the chain of symptoms which usually accompanied these cases and was treated by various physicians for neurasthenia. On opening the abdomen he found he could not get to the head of the colon unless he broke through a number of adhesions to reach the pericolic membrane which extended clear over, and when he got down to where the appendix was he found it was normal, within a sac, and was not adherent to the tissues around it. The appendix was free, and the pericolic membrane spread over it, with the head of the cecum plastered down upon the parietes.

**Landry's Paralysis.**—Dr. E. M. HUMMEL of New Orleans reported a case of Landry's paralysis in a man, 46 years of age, which gave strong support to the opinion that lowered resistance was the preliminary necessity in the development of the disease, and the agency of psychic depression was again introduced. While no specific organism was likely to be proven the cause of Landry's paralysis, it seems that some condition of toxicity springing out of unwonted virulence of some one of the bacterial flora native to the body and operating under the auspices of lowered resistance would be settled upon as the cause of this insidious, creeping death, for such might it be characterized in its clinical expression.

Dr. A. L. SKOOG of Kansas City, Mo., said the mortality from Landry's paralysis ranged from 75 to 100 per cent. Landry's paralysis was prone to occur in adult life. Children were less frequently attacked than adults. There was a group of acute poliomyelitis cases which might be described as the neuritic type, and in some of these cases beginning as neuritic types the disease might ascend and be called the neuritic plus the myelitis type. Psychic depression and also physical exhaustion had been named as predisposing causes. It was known that with mental and physical fatigue infectious processes were more likely to be engrafted upon the individual. He thought this had been shown in some animal experiments, with no bacilli present. Those who had done laboratory work, especially in the last few years, with acute poliomyelitis thoroughly believed that it was due to some infectious process. Very recently Flexner and Noguchi had reported an organism as the cause of acute poliomyelitis, which they thought they had isolated and cultivated. It was too early to say they were correct, but he was inclined to believe they were. In view of what was known of acute poliomyelitis, that it could be transmitted to monkeys, it was of considerable interest to have a few cases with frank symptoms of Landry's paralysis and attempt to inoculate animals.

Dr. C. R. WOODSON of St. Joseph, Mo., said there could be no question but that there were cases of Landry's paralysis in which there was elevation of temperature and sphincter involvement. Some writers were disposed to believe that the disease was a polyneuritis. However, it had some characteristics which were quite different from the ordinary types of polyneuritis and some types which were very much like it. The symmetrical symptoms were quite like those of multiple or polyneuritis. Oftener in poliomyelitis there was a lack of symmetry. There was no question but that we had a flaccid paralysis in poliomyelitis. With poliomyelitis the arterioles were involved. In Landry's paralysis the spinal ganglion was implicated. According to some authors there was a disseminated myelitis. Again, there was occasional recovery in cases of Landry's paralysis, but he did not recall any author at the present time who said complete recovery followed in cases of disseminated myelitis.

Dr. C. C. GODDARD of Leavenworth recalled the case of a physician who was perfectly well apparently up to a certain evening, when he reached out his hand to take hold of the ear of his dog and found he could not hold it. He tried several times to do so. Then he tried with the other hand to do so and found he could hold the dog's ear all right. The patient was prison physician. After a time he began thinking about his condition and tried to pick up different objects and hold them, but he could not do so. He could move and flex his fingers. The next morning the left arm was paralyzed. The other arm became involved. That day he thought he was bound to get out of bed. He threw himself out of bed and fell to the floor. The speaker was called in and made a diagnosis of Landry's paralysis or acute ascending paralysis. The patient could move his feet in bed that day, but from that time he became completely paralyzed, both as to sensation and motion in his whole body. It started in the left arm, which was unusual, as it generally began in the feet. The mind was perfectly clear; his pupils looked all right at the time he went to bed. He had no pain; he had to be catheterized; he could not pass urine after the second day without catheter. After the fourth or fifth day paralysis of deglutition set in; his pulse became weaker and weaker; he gave a sighing respiration and was dead.

Dr. CHARLES O'NEILL RICH of Omaha reported the case of a postman who was admitted to the hospital complaining of numbness in both feet. He gave a history of sore throat. Paralysis was progressive. At the time poliomyelitis was attracting a great deal of attention and he tried in some way to correlate the two diseases. A diagnosis of Landry's paralysis having been made, he made spinal punctures every six hours and a blood count. His sphincters were intact, and the only thing very noticeable was the ascending paralysis. His blood count during the eleven days he was in the hospital ranged from 8,000 to 16,000. His spinal fluid ranged from 60 to 96. The lymphocytes per c.c. were much the same as in the cases of anterior poliomyelitis reported at the time. He tried to get a monkey for inoculation, but was not successful. Toward the last the lymphocytes in the spinal fluid had increased. He had a Noguchi positive, a negative Wassermann, and negative lues. The majority of clinicians and pathologists considered Landry's paralysis as identical with anterior poliomyelitis, but coming on as it did in adult life, and death occurring at such an early stage, the patient did not get the resulting polyneuritis, but simply a root lesion and ganglion lesion.

Dr. S. Grover Burnett of Kansas City, Mo., said Landry's paralysis involved the muscles of the legs, the trunk, the arms, the respiratory muscles, and the throat muscles, and the story was usually ended. The patient did not die from toxemia but from the want of air. He died because he had become paralyzed so far as respiratory function was concerned. He had seen but one case recover. It was a question whether or not he was correct in his diagnosis. May be he was not, but the patient got well. The disease began in the lower extremities, took the usual course, extended up and involved the throat muscles. The paralysis was progressive from one six hours to another. In desperation he gave dram doses of fluid extract of ergot every three hours. Under the influence of the ergot the disease seemed to be checked; but, on the other hand, it was known that this happened once in a while, and a few patients got well. Possibly this was one of those cases, and that he was mistaken in his diagnosis; but he was a good Missourian, he had to be shown.

Dr. Abraham Sophian of New York City stated that from the studies that had been carried on during the past few years, particularly with reference to clinical and laboratory analyses, the relationship between Landry's paralysis and poliomyelitis had been established, and there was no question but that in some instances Landry s paralysis and poliomyelitis were one and the same disease. Several years ago he studied a large epidemic of infantile paralysis in New York City. During this epidemic he had occasion to see two cases of Landry's paralysis in children. Incidentally the cases of poliomyelitis occurred at all ages, the youngest child being one year old, and the oldest man was 35 years of age. Poliomyelitis was characterized by two great symptoms, first the motor, that is, the paralytic phenomena, and secondly the symptoms of hydrocephalus. Landry's paralysis had both of these symptom-complexes. We had hydrocephalus in all cases of Landry's paralysis. Poliomyelitis might affect any part of the central nervous system. The characteristic feature of Landry's paralysis was the ascending paralysis. The cerebrospinal findings in the two diseases were similar.

**Rheumatism.**—In a symposium on this subject several papers were read in which the various theories as to the etiology of the disease were advanced. The diagnosis of chronic rheumatism, the modern conception of rheumatism, and its treatment were discussed. In the diagnosis chronic disease of the joints was considered a sign of some focal or systemic disease elsewhere in the body. The diagnosis of chronic disease of the joints depended upon establishing the interrelationship between the focal and systemic disease and the changes in the joints. In the cases observed by the authors treatment directed toward these focal or systemic causes produced the best results upon the joint lesions.

**Cancer.**—In another symposium on cancer, Dr. W. L. Brosius, Gallatin, Mo., spoke of the theories of Virchow, Rous, Ross, Wassermann, Loeb, etc., as regards the etiology of cancer. Dr. Joseph C. Bloodgood, Baltimore, pointed out the great danger of incomplete operations for cancer in the early stages; while Dr. Franklin H. Martin, Chicago, discussed the early diagnosis of cancer of the uterus and its surgical treatment. Other papers presented dealt with cancer of the stomach from a medical point of view; prevention and treatment of cancer of the skin; cancer of the colon from a diagnostic point of view; surgery of the axilla in advanced mammary cancer, and the *x*-ray treatment of cancer.

Dr. John F. Binnie of Kansas City, Mo., said that too much abuse had been poured upon the unfavorable statistics after operative treatment for frank malignant disease in the matter of recurrence. He thought other terms should be used. After cutting out disease, if we had a reappearance of the disease within a comparatively short period of time, say after two or three years, it was a true reappearance of the disease, but it was not a recurrence. It meant some disease was left and still continued to grow, but when we had a true recurrence things were somewhat different. If disease appeared again after a lapse of three years why could it not be the original causes of the disease working again on a patient who had shown himself non-resistant to the noxious influence which caused disease, and we had a fresh incidence of the disease, not necessarily a recurrence.

Dr. J. P. Kanoky of Kansas City, Mo., said that where the cancer was very malignant and affected the deeper tissues, the *x*-ray would afford relief, although it might not cure. As regarded superficial ulceration or rodent ulcer years ago he employed the actual cautery or the knife. Within the last few years he had used carbon dioxide snow. It was as efficacious as the cautery, much pleasanter than the knife, and the cosmetic results were superior to both. Superficial cancer or so-called rodent ulcer could be treated by means of carbon dioxide snow with absolute success.

Dr. Henry S. Munro of Omaha believed in every therapeutic measure that would help a patient, but in the consideration of any method of treatment one must see the entire individual, and we could not look upon any particular part of the body alone. Just in proportion as we went into the life of the individual and studied him physiologically and psychologically could we help him by increasing his power of resistance to the onslaught of the parasitic cells.

Dr. H. M. Lyle of Kansas City, Mo., said there were some types of epithelioma which the carbon dioxide snow would cure, but he would not depend too much on it because it was too superficial in its action. In using the *x*-ray there were several things that came up which the individual operator had to watch for in the way of protecting the patient, in knowing how much the individual patient would stand; he meant by this that the dosage should be gradually increased. It had been his experience that it was well to begin with short treatments and give them often until one found just exactly how the patient was going to stand the effect of the *x*-ray. Other radiographers gave one or two large doses of from fifteen minutes to half an hour's treatment. If this was done, he believed one did more harm than any good he accomplished. In regard to thoriamdin paste, which was put out as a radioactive paste, it was the combination of nitric and sulphuric acid in it which acted as a cauterant and hence one got an effect from it. He did not believe, however, there was any thorium in it to give any beneficial results outside the cauterization.

Dr. Rollin H. Barnes of St. Louis did not think we were able to diagnose cancer of the colon sufficiently early to expect the promising results which we could obtain from cancer in some other locations of the body; but we should carefully observe those patients who showed the least indication of trouble in this region and always keep in mind cancer.

Dr. W. O. Henry of Omaha spoke with reference to enlightening the laity about cancer of the uterus, and said that committees had been appointed by various societies in the United States to do what they could to enlighten the people. Physicians who were abreast of the times, who attended regularly city, county, State and national meetings were pretty well informed; but there was a large class of physicians who did not attend these society meetings, and who did not read up-to-date medical journals. It was those men that should be educated as well as the laity, and the way to do it was for every State society to have a publicity committee, backed by the authority of the society, to prepare proper articles for the publication in the daily press and also to be supplied to the weekly papers in every county.

Dr. A. L. Blesh of Oklahoma City wondered how we were going to educate the people upon the cancer question when perhaps nine out of ten of the deep body cancers could not be diagnosed by the physician himself in time to be of any avail whatever to the patient. Only a few days ago he examined a woman sent to him by a brother physician. He found far advanced cancer of the cervix. In operating he found the disease had extended so far out into the sides of the pelvis retroperitoneally that he gave it up in despair and closed the abdomen. How were we going to educate the people to consult physicians for cancer, Dr. Blesh said, when they did not know that the disease existed?

Dr. Donald Macrea of Council Bluffs, Iowa, said this and other societies ought to take a strong stand with regard to a publicity campaign in educating the laity about cancer. In the country the majority of cases of cancer were seen too late to do much, if any, good. The right time to operate on these patients was in the precancerous stage.

Dr. H. C. Crowell of Kansas City, Mo., said if one thing was of greater importance in regard to cancer than anything else it was the education of the people secondarily and the profession primarily. The average physician of the country was better informed on the scientific methods and procedures and the advanced treatment and advanced theories of cancer than he was on the diagnosis. He knew from experience patients were treated and treated by this physician and that physician without a diagnosis of cancer having been made, when patients should have been subjected to some means by which the diagnosis might have been made early enough to eradicate the cancer.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held March 6, 1913.*

THE SECOND VICE-PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

**Devices for Artificial Respiration.**—Dr. SAMUEL J. MELTZER presented this paper. After speaking of the progress made in dealing with temporary failures in respiration and referring to the methods of Schafer and Sylvester, he expressed his preference for the latter method. He stated that he suspected that there were a fairly large number of good medical men who were unprepared to perform either of these methods efficiently. Every medical man should possess the knowledge of and some dexterity in handling life-saving methods in emergencies. In neither the Schäfer nor the Sylvester method could the respiration be kept up sufficiently long to keep the circulation going for hours. Hence a hunt had been made for efficient devices for artificial respiration. Dr. Meltzer said that as he was on the committee appointed by the Bureau of Mines to investigate such devices he was not at liberty to express his opinion of their actual value before the entire committee sent in its report, but he would say that he had been impressed with the idea that the invention of other devices had not been made superflous by the existence of those already on the market. Dr. Meltzer then described his method of pharyngeal insufflation which had given very satisfactory results with animals, but which, when tested upon dead human bodies, was found to permit the escape of air through the nose and mouth. This could not be prevented in the human subject in the same easy manner in which it had been accomplished in animals. He had since tried to perfect the pharyngeal method so as to adapt it to the requirements of the human anatomy. Simultaneously he had studied the efficiency of carrying on the respiration by means of a well-fitting face mask. In both methods a heavy weight had to be put on the abdomen and reinforced by the application of a tight bandage. This prevented the entrance of the accumulated air into the gastrointestinal canal. This restricted abdominal respiration and was probably of service to the failing circulation by driving blood from the paralyzed blood vessels of the splanchnic region into the heart and medulla oblongata, where it was most needed. In both methods the external arrangement for an efficient rhythmical and safe control of the respiration was the same. It consisted of a source for gas or air pressure, of a valve attending to the rhythm of respiration, and of a safety valve. The point which differentiated the two methods was that for the pharyngeal method the pharyngeal tube which he had now devised was of fairly large transverse diameter and capable of filling out the entrance into the pharynx so that the insufflated air could not escape so readily back through the mouth. The pharyngeal end of the tube was cut off slantingly, so that when inserted into the pharynx the end of the lower wall remained anteriorly to the opening of the larynx, while the upper wall extended to the posterior wall of the pharynx, raising the soft palate and the uvula and thus shutting off the oval pharynx from the nasal cavity. The method of using the apparatus was as follows: After the abdomen was well weighted the tongue was pulled out, the mouth opened widely and the pharyngeal tube inserted as far as it would go. The neck of the pharyngeal tube should then be connected with the bellows or oxygen tank. As soon as the air or oxygen was turned on a person grasped the respiratory valve, turning the ring from side to side, every three or four seconds, and thus an efficient respiration was on. Instead of the pharyngeal tube a tightly-fitting mask with a nozzle for connection with the blowing apparatus, tightly and safely attached to the head, would do efficient service. In either case the tongue had to be kept well pulled out to keep the epiglottis raised and the entrance into the larynx free. He believed that the respiratory changes could be accomplished with greater readiness by the pharyngeal method than by the face mask. The Schäfer method could easily be combined with either of these methods.

**Treponema Pallidum in the Brains of General Paralytics.**—Dr. HIDEYO NOGUCHI made a demonstration of the *Treponema pallidum* in the brain in cases of general paresis, with lantern slides.

**Protein Assimilation.**—Dr. DONALD D. VAN SLYKE read this paper. He first referred to the structure of the amino acids which were the units or building stones out of which the protein molecule was constructed and the final products obtained when the proteins were hydrolyzed by strong acids or by the action of pepsin, trypsin, and erepsin in the alimentary canal. The characteristic point was the occurrence in the same molecule of an acid group, with an acidity like that of acetic acid and an amino group, with a basicity like that of ammonia. The acid and the amino groups were joined by a central carbon atom, which served as a bridge between them. Of the many characteristics of this molecule was the one which made the existence of protein and of protoplasm possible, that was the ability of the amino acids to dovetail themselves together and thus form a chain of indefinite length. When the proteins were attached, by trypsin, for example, the links of the chain were broken apart and there resulted shorter chains, the albumoses, then still smaller ones, the peptones, and finally the separate amino acids. This constituted the process of digestion. The formation of new protein consisted of the reverse, namely, the linking together of the acids into new chains. The problem to be considered was that of tracing the proteins of the food from the alimentary canal through the blood stream into the tissues and there ascertaining their final fate. The author reviewed four theories which had been advanced to explain the mechanism by which the food proteins reached and were utilized by the tissues of the body, and pointed out wherein they had failed to stand the tests applied. He stated that the entire confusion and controversy had been due to the failure to apply methods which were sufficiently accurate and sensitive to determine whether amino acids and proteins were or were not present in the normal blood, and whether they passed into it from the alimentary tract during digestion. During the past three years they had developed in their laboratory a method which it seemed might solve the problem. When amino acids were brought into a solution of nitrous acid under proper conditions, an almost instantaneous decomposition of the amino group occurred and its nitrogen was evolved in the form of an elementary nitrogen gas. This gas could be measured accurately and afforded a delicate means for detecting amino acids in even minute quantities. With this method Dr. Gustave Meyer and the author began to experiment a year ago in order to determine whether the digestion of protein caused amino acids to appear or increase in the blood. The results of the experiment were speedily positive. They found that the blood of a dog always contained a small amount of amino acid nitrogen, and that this amount could be more than doubled by feeding protein. The concentration of the amino acids in the blood was small even at its maximum; the concentrations found were entirely sufficient to account for the most rapid imaginable absorption of proteolytic products. It was now certain that digestive products were taken directly into the blood, and, although the possibility of some synthesis in the course of absorption had not been excluded, there was at present no reason to believe that any such roundabout mechanism played an important part in normal absorption. From the low amino nitrogen content of the blood, it was apparent that if all the digestive products entered the circulation they must be removed from it very rapidly in order to keep their concentration so low. To test the rate at which the removal occurred they injected 12 grams of alanine intravenously into a dog. The nitrogen was nearly 2 grams, an amount which in the form of protein could keep the animal in equilibrium for a day, yet in five minutes after the injection 88 per cent. of the injected amino nitrogen disappeared from the circulation and after one-half hour the amino figure of the blood had dropped to 12 milligrams which was about normal for a dog in digestive activity. They had repeated the experiment with mixtures of all the amino acids yielded by the hydrolysis of casein with absolutely similar results. It was probable that in the case of man, where relatively moderate amounts of protein entered the diet mixed with carbohydrates and fats and divided into three or more meals per day, the fluctuations during digestion were less than those observed in dogs after heavy meals of meat. The question next arose as to what became of these products when they vanished from the circulation. Because of the velocity with which the amino acids disappeared from the circulation, it seemed that a physical explanation was more probable than a chemical one. They therefore analyzed the tissues after known amounts of amino acids had been injected and observed to disappear from the circulation, and found that they were, in fact, merely absorbed by the tissues, and that, as nearly as could be estimated, all the injected amino nitrogen was found again in the muscles and other organs. It would be seen that the tissues, even in a fasting animal, were about ten times richer than the blood in amino acids. When the concentration of the latter in the blood was

increased by injecion, absorption into the tissues immediately occurred, and led to new equilibrium between the blood and the fixed organs in respect to the content of both in amino acids. That a state of equilibrium did exist was indicated by the fact that, notwithstanding the extreme avidity of the tissues for these products, they never entirely removed them from the blood. When, as a result of an injection, the concentration of an amino nitrogen in the tissues rose to a higher level, the ultimate concentration in the blood also remained at a higher level than before the injection. Another point worthy of note was that in the case of muscles a fairly definite saturation point existed which set the limit to the amount of amino acids that could be absorbed. They had never been able to force the amino figure of the muscles above 75 milligrams per hundred grams of tissue. The statement that the amino acids entering the blood stream were merely absorbed without chemical alteration by the tissues was a very loose description of a phenomenon for which the complete explanation would be far from easy. After advancing several theories as possible explanations, he stated that the solution of this phase of the problem would have to be left to the future, and at present merely designated the phenomenon of absorption. They had undertaken experiments to determine for how long a period the amino acids could remain unaltered in the tissues and found that the amino acids disappeared from the kidneys at a rate incomparably greater than that at which they left the muscles, or apparently the other organs analyzed at the end of the experiment. In the muscles, on the other hand, the drop was so slight that it hardly exceeded the differences which could normally occur in different sections of the same organ. The disappearance of amino acids from the liver and kidney was accompanied by an increase in the urea content of the blood. These facts strengthened the old view that the liver was to an especial degree active in transforming the products of protein digestion into urea. It was somewhat surprising to note a similar disappearance of amino acids from the kidneys. Further experiments seemed to show that, while the muscles after a heavy feeding of meat were stored with amino acids up to their saturation point, the liver and kidneys metabolized their portion of the products as rapidly as they received it. When the other tissues became saturated it was possible that the entire task of removing the digestive products from the circulation fell upon these two organs, and that most of the proteolytic products which they took up were normally broken down, the nitrogen portion being transformed into urea. This hypothesis would explain many previously known facts. The work was still far from finished; as yet they had gained no intimate knowledge of the mechanism by which the body built its new protein and they had touched only one-half of the problem, that of the fate of the nitrogen part of the amino acids. The fate of the remaining portion offered a more complex problem.

Dr. L. F. Bishop said that Dr. Van Slyke's paper was too important to be passed without commendation. In the discussion of the speaker's paper before the International Congress of Hygiene on "The Prevention of Arteriosclerosis," Dr. Mendel called him to account for predicating the existence of amino acids in the blood. This was only last September. He had been making an intensive study of arteriosclerosis for the past three months in the preparation of a book, and had sought and obtained the opinions of a good many men. He believed arteriosclerosis was a disorder of the ultimate cells of the body in which the blood vessels took an important share. The cells became sensitive to particular proteins, and this originated a subsymptomal reaction that caused the damage. Dr. Van Slyke's discovery of the lodgment of the amino acids in the tissues so quickly that their detection in the blood was difficult was of extreme interest and Dr. Bishop said he felt a personal debt of gratitude to Dr. Van Slyke for the help he had given him in the problem of arteriosclerosis.

**Studies in Experimental Pneumonia.**—Dr. Martha Wollstein presented this communication. She stated that the production of a disease experimentally by its specific organism was one of the most convincing arguments in confirming the relation of an organism to a disease. The vast majority of endeavors to produce pneumonia experimentally had been failures. At best they might be compared with the injections of typhoid bacilli which produced infection but not typhoid. The one exception was the work of Wadsworth based on the theory that the failures to produce lesions in pneumonia in animals were due to the fact that the various species were either insusceptible or hypersusceptible to the pneumococcus. Their experiments had been made with a new method and had been used in more than two hundred and fifty experiments with practically uniform success in animals which were very slightly susceptible to pneumococcus infection. The following simple method was used: With the animal under ether a long rubber catheter of small diameter with an opening at the end was introduced through the mouth, larynx, and trachea as deep into the bronchus as it would go. By means of a sterile pipette and syringe a certain quantity of culture was then injected through the catheter. In experiments upon 44 dogs there were only two failures which were probably due to some error in technique. All the other dogs had pneumonic lesions perfectly comparable with the lesions in human lobar pneumonia. Seven of the animals died with bacteremia, empyema, and pericarditis. In the animals which recovered the lesions resolved in six or seven days. There was no chill at the beginning of the infection and no crisis at the end. A few hours after the injection a moderate rise of temperature occurred and gradually disappeared in twenty-four to thirty-six hours. In fatal cases there was a second rise of temperature. In non-fatal cases there were practically no symptoms comparable with those generally present in human pneumonia. In a few experiments made by Lamar and Meltzer with Friedlander's pneumobacillus and with the streptococcus mucosus the results were practically the same as those produced with the pneumococcus. During the past fifteen months several series of experiments had been carried out by the same method using various organisms and in two instances a virulent and a non-virulent strain of the same organism. By insufflation with ether and the removal of the sternum and several rubs they had been enabled to follow the development of the lesion from the beginning of engorgement until hepatization was well established and fibrin flakes were present on the pleura. In one series of experiments they studied the eect of intrabronchial insufflation of cultures of streptococcus and of the influenza bacillus. In both instances a lobular pneumonia resulted, anatomically similar to lesions well known in human pathology. There were no fatal results and the clinical course of the disease was about the same as that seen in the non-fatal pneumonias produced by intrabronchial insufflation of pneumococcus cultures. The pathological differentiation in the character of the lesions produced was unmistakable. The intrabronchial insufflation of the pneumococcus, the pneumobacillus (Friedlander), and the streptococcus mucosus caused pulmonary lesions of the character of lobar pneumonia with an abundance of fibrin and with slight tendency to invade the lung framework. The insufflation of the *Staphylococcus aureus,* the streptococcus, and the influenza bacillus caused a lesion like that found in bronchopneumonia, containing only a moderate amount of fibrin and with no tendency to affect the pleura, but invariably showing a leucocytic infiltration of the framework of the lungs. In other series they studied the influence of the virulence of the organism upon the nature of the lesion. Using a non-virulent organism of pneumonia they again succeeded in producing well marked pneumonic lesions in dogs. The gross appearance of the lesion was that of a mild lobar pneumonia differing from the lesion caused by the virulent pneumococcus in the smaller amount of fibrin present and in the absence of pneumococci from the blood. In the animals which received cirulent pneumococci they invariably found pneumococci in the heart's blood; while in the series of experiments with the non-virulent strain, pneumococci were not found in a single instance. The same difference was found to obtain between the effects of the virulent and non-virulent streptococci. The intrabronchial insufflation of such a harmless saprophyte as *B. megatherium* caused a pneumonic lesion practically similar to that produced by a non-virulent pneumococcus, a mild lobar pneumonia with very little fibrin and no bacteriemia. The insufflation of virulent pneumococci killed by heat caused only a moderate hyperemia. Practically the same result was obtained when sterile broth was injected. All of these results were obtained by intrabronchial insufflation and could not be obtained by mere injection or insufflation into the trachea. Their theory to account for this was that by the intrabronchial injections a number of terminal bronchi were converted into closed tubes filled up with the culture. The mere presence of pathogenic organisms upon a free surface did not lead to an infection; to be successful the organism had to be entrenched in a closed tube or cavity, or in an ulcerated surface where they could creep under cover or hide under a dead tissue. It was possible that this was the history of non-experimental pneumonias in human beings.

After an insignificant laryngitis or bronchitis some mucus filled up small bronchi without causing any noticeable symptoms, but now and then virulent pneumococci might get there, multiply, and suddenly be in a position to attack the lung structure. The fact that the virulent strains of bacteria were found in the heart's blood in the first two days after the injection, although the majority of these animals survived, might justify the statement that the presence of the organism the blood in the early days of the disease did not indicate that the organism was of a virulent type, while it might be freely admitted that the presence of the organism in an advanced stage of the disease suggested rather an unfavorable prognosis. All the animals which died of experimental pneumonia had bacteriemia.

---

SECTION ON PEDIATRICS.

*Stated Meeting, Held January 9, 1913.*

Dr. Henry Dwight Chapin in the Chair.

**Remarks Concerning the Need of Psychological Clinics in Connection with the Public Schools.**—Dr. L. Pierce Clark read this paper. He said that for years there had been a growing discontent in the minds of the thinking public with the slow advance in individual teaching in the public schools and one of the comparative new departures to meet this lack had been the establishment of ungraded classes for the so-called subnormal children. This work had advanced very rapidly, there being to-day, in New York City alone, 152 ungraded classes caring for over 2,700 pupils. It is now estimated that there were 7,000 children in New York in urgent need of such instruction as was given in these ungraded classes. At least 427 classes were needed for this work. This did not mean that feeble-mindedness was on the increase in the public schools, but it simply meant that the public was awakening to the importance of detecting these defects in the pupil material of the public schools. The importance of this work could not be questioned. The withdrawal of the mentally unfit or deficient child from the normal class was alike beneficial to the normal and to the subnormal child. The idiots and imbeciles might be receiving much good from these special classes, but all were agreed that they needed special institutional training in colony homes where proper habits of living and work for the whole of life might be taught. This hopeless and but slightly educable class must be cleared from the schools. Until the State was prepared to care for them there was no doubt but that these defective children should remain in the ungraded classes, getting as much as possible of the social education which had been patterned after the institutional plan of instruction. More exact psychiatric analyses of these high-grade defectives should be made. The neurotic, nervous, emotional child, given to day dreams or night terrors, or suffering from memory or attention defects, the child with uncontrolled tics and habit spasms, or even more pronounced nervous or mental disease; in fact, the whole group-class which formed the embryo storehouse of the psychoneuroses and the near invalidism of later life, should be more carefully studied. They, as physicians of special neurological and psychiatrical training, should not be slow in recognizing that this was a special field for the study of the causation and prevention of the functional nervous diseases. Still more fundamental would be the study of the makeup of the neurotic constitution which all were agreed was the core of the neuroses. It might be just possible when this nucleus was disclosed that it would be found that it acted as a Mendelian unit and was just as transmissible as physical defects, were known to be. Out of this neuropathic constitution flowed the antisocial traits of abnormal child life, such as lying, stealing, truancy, sex-perversion, and a host of others. It was estimated that this class of children formed from 5 to 10 per cent. of all school children. Many of these children grew up into healthy men and women in later life. If it had taken years of painstaking study to evolve a comprehensive understanding and training treatment of the frankly defective child, how much more labor remained to be performed before they would reach an understanding of these deviate children of the neurotic type? The problem of establishing psychobiologic clinics was not a new one. They were a step in the right direction, but the psychologic clinics needed expert psychiatrists and neurologists to extend and make definite a form of psychoanalytic inquiry commensurate with the newer methods in psychiatry. The need of the present was not a lot of cases loosely studied, but a few cases carefully and exactly analyzed. The reason for establishing such clinics in the schools was that the schools were established and had the full confidence of the parents and could readily incorporate a complete and properly equipped clinic with their other special schools for the blind, deaf and mute, and crippled. Such a clinic should have a definite record of the child's defect and behavior in a false adaptation or lack of progress in the normal school; there should be careful research of the family life and environment which might be a contributing cause for the nervousness; there should be an intelligence, will, judgment, and ethical test by trained experts as well as a thorough physical examination. Then, and not until then, should a prescription of the special school treatment be given. Provision should be made for a follow-up record and for re-examination. The case should be reviewed after a certain observation treatment had been applied. A system like this called for team work on the part of the teacher, psychologist, neurologist, psychiatrist, and sociologist. There was work and honor in such a field of endeavor. Such a clinic was being organized for the New York City schools and they hoped to show some important results in solving this problem.

**Etiological Factors in Atypical Children.**—Dr. S. P. Goodhart presented this paper, in which, he said, he would use the term atypical in its most significant and broadest sense as referring to that class of beings, who, by reason of unstable or rather disproportionate mental faculties, did not conform to the ordinary accepted standard. This class should be differentiated from those mentally defective, as the dullard, the imbecile, or the idiot. The atypical child might often be endowed with qualities of genius or a special aptitude in certain directions. In these children it had been found that heredity played an unquestionable etiological rôle. There was a history of syphilis, alcoholism, epilepsy, consanguinous marriage, or a psychosis of some kind. These children were usually deficient in certain practical elementary intellectual qualities. If improperly educated or brought up in unsuitable surroundings these children often developed criminal traits for which society paid the price of ignorance and neglect. In adult life these individuals often found themselves out of tune with their surroundings, lost the incentive of life work, and their mental attitude was in conflict with the conditions life imposed upon them. Eventually there was forced out another and weaker personality. In the soil of such conditions lay the seed of dementia precox. The influences of the experiences of the early years upon the development of the various forms of the neuroses later had been emphasized during the last decade by the methods of psychoanalysis. Investigations had shown that the experiences of child life which formed the nucleus for functional neuroses later in life need not be of sexual color, but that any form of psychic trauma, attended by strong emotional reaction, and suppressed, might suddenly emerge as the basis for severe psychic disturbance. Sublimation, that was the transforming of the energy of the sexual impulses into productive activity, should begin early in the child's life. The necessity of carefully observing evidences of the tendency to sexual perversion in children should be appreciated. Dr. Goodhart said that personally he believed that there were bisexual elements in all and that the development of the invert was probably due to some one profound or perhaps repeated sexual experiences among children of the same sex. The development of the will should be specially directed to overcoming the obstacles of life experience. The need of this was made evident by what was known as regression, meaning the turning back of the energy of the individual to the primitive, the juvenile habits of thought and action. The neurosis often appeared in the later life of the neurotic, when confronted by what appeared an insurmountable obstacle, effort was abandoned and the psychic energy became anchored to its juvenile phantasies. The tendency of the imaginative child to become self-centered and thus have his perceptions aroused by autoerogenous stimuli should be combatted. If allowed automatic repetition, complexes formed, the sexual perversities adhered to the subconscious, and, in time of regression in later life, became active phantasies around which the neurosis developed. The unstable neurotic type must be differentiated from the self-controlled child, the one who had himself well in hand, who had a specially vivid imagination with a mild tendency to day dreaming, a fondness for solitude and reflection was extremely sensitive and apparently timid. This child was liable under unsuitable environment to develop into the truly neurotic. The routine pedagogical systems were entirely unsuited to the education of the atypical child. An effort to educate these children according to the accepted system resulted in placing them in the

category of the seriously deficient, rapidly depleting their energy in fruitless effort, and finally ending in serious mental conflict. Adequate psychological pedagogy, adapted to the individual, could be applied, as were orthopedics and gymnastics to the physical inefficiencies. Psychological clinics were needed with social workers whose functions would be both scientific and practical. Trained psychopedagogues would often detect the pre-dement or pre-paranoic. The years of adolescence were fraught with great danger to the psychic life. Imagination and introspection became heightened in the neurotic child, and, as in the psychology of precox, the horizon of mental activity became more circumscribed. The child might delight in the illusory life, made up of complexes, that by repetition took form and root, later, perhaps, to become the nucleus of true paranoid entities. The exaggerations and perversions of the normal psychological perceptive and apperceptive processes, or the persistence of those which should be modified or assimilated by experience and development of the intellect, brought one close to the question of how far psychological pedagogy could save the child. There was a class of children having, as a rule, the hereditary taint, who were intellectually up to the average, but who had an intense emotionalism. They might suffer from seizures of epileptoid nature, but the earmarks of true epilepsy were wanting. The attacks might occur during the first decade, perhaps only once, or they might be recurrent for years without any psychic deterioration. Unless the proper adjustment was made in the environment of such children, their late life showed the deflections of the psychasthenic. Many of the symptoms of dementia precox were really perversions or exaggeration of normal mental juvenile life. Dr. Goodhart said he had found the Binet tests of general value only: they were doubtless useful in schools and institutions. They did not allow one to reach the child's true emotional sphere or to reach conclusions as to the relation between judgment, memory, and emotion. While it was true that moral development was largely a matter of education, there were children who were really moral imbeciles. It was surprising how frequently one met with true paranoid psychological elements in the neurotic child. Even here, early training, the cultivation of self-restraint, might develop inhibitory powers which would enable the patient to govern impulses which held sway over morbid ideation. From this material the more intelligent criminal class, the harmless cranks, and the homicidal often took their origin. In spite of the fact that heredity was a powerful factor in both physical and mental disease, man probably did not enter the world with an unalterable fate of mental deterioration. Through the application of Mendel's law some of the irregularities of transmission in heredity were coming to be understood and psychoanalysis gave a method for the study of subconscious activity, a phase of mental operation that exerted a tremendous influence upon the conscious activity of the individual. It would seem that many of the obscure problems of inheritance were to be accounted for through the operation of subconscious mind. Dr. Goodhart emphasized the great importance of deep emotional complexes that had been relegated to the subconscious during early life. Those who had studied ancestral and personal histories of a very large number of defectives found syphilis a very prominent factor in the etiology and doubtless this was true for the neuroses. As to consanguinity, it seemed that the character of the stock was the determining factor. Consanguinous marriages between those of good stock resulted, as a rule, in high-class offspring, but if a neurosis was introduced the offspring suffered more than from an indifferent mating. Etiologically the social and economic problems, in every aspect, bore directly upon the production of mental deviation and its development even in healthy children. Dr. Goodhart did not believe that sterilization was the cure for crime; one had to go back of those already afflicted. The individual conscience must be awakened so that general laws of mental hygiene would be enacted and carried out under the supervision of competent scientists. Then only might they hope to be relieved of the fruitless burden of caring for mental and physical anomalies.

**The Mental Defective and Society.**—Dr. William Leland Stowell read this paper. He stated that by the mental defective in his paper would be understood the feeble-minded person. The family physician was the first to see the mental defective at the age of one or two years when the family first began to realize that the child was not normal. Perhaps the child failed to grasp objects at the age of six months, failed to show surprise or fear, failed to begin to walk at the age of one year, to show curiosity, or sociability at the age of a year and a half, or to talk at twenty months, and continued infantile habits beyond the age of two years. At the age of six or seven the school teacher noticed the limitations of such a child. He could not learn the use of objects, could not tell time, or age, or count, or appreciate form and color as normal children did. If his intelligence never got beyond that of a child of two years he was an idiot; if only to that of a child of seven, he was an imbecile; if he stopped developing at the age of twelve, he was feeble-minded of high grade; if almost up to the standard he was a moron. The feeble-minded child could not compete with normal children, because he lacked reasoning power, did not appreciate right and wrong or the consequences, was actuated by impulse or suggestion rather than by design. He lacked imagination, power of initiative, and that of prolonged application. Such persons had little moral sense and sexually were corrupt. While they lacked judgment they might develop some faculty to a specialty. Carefully gathered statistics had enabled them to compute that at a conservative estimate there was one feeble-minded person to every 300 normal individuals, or 300,000 feeble-minded individuals in the United States. There were 30,000 of these persons in New York State and less than 4,000 of them were in four proper institutions. Only twenty-three of the forty-eight states had suitable institutions for the feeble-minded at present. The author's experience had been gained at Randall's Island, where there were 1,186 aments. Here they tried to supply them with a proper environment. The girls were taught sewing and domestic employments and the boys were instructed in trades and outdoor work. In the schoolroom the work was one under the supervision of normal minds. They could not supply gray cells where none existed and hence such children should remain with their peers in an institution. There they should be taught personal cleanliness and put through a modified kindergarten course. The education of the borderline cases had been greatly advanced during the last decade. The special classes maintained by the New York City Board of Education were doing a most useful work. However, this work was not for the public schools, for scarcely one-tenth of the children ever rose to normal grades. These children should be in an institution all of the time instead of in the public school for a part of the time. The adults should be segregated because of the likelihood of their becoming parents of their kind. Again, this class of individuals were happier when with their kind because they were not fitted to compete with normal individuals. Segregation was especially necessary for feeble-minded girls, because of their lack of moral force, most of them becoming mothers early in life. The author gave statistics showing the high birth rate among these defectives, the average being six children per family, whereas the average among normal American families was three children. He also showed that feeble-mindedness was two-hundred times as frequent among prostitutes as among normal women. After referring to the famous Jukes family and the Tribe of Ishmælites in Indiana, the author emphasized the fact that such histories could be prevented if proper prophylaxis was applied. In this State they had, happily, one institution where 800 women were safe from motherhood. Feeble-mindedness was an incurable condition and not a disease. The condition of the higher grades of feeble-mindedness could be improved by training so that they became useful in institutions but not capable alone. Dr. Caldecot, of Earleswood, in an investigation of 341 patients who were discharged during fifteen years, found that 3.25 per cent. were earning wages, 3.81 were at home very useful, 7.5 were at home and useful, and the remaining 85.5 per cent. were of no good whatever and should have been taken care of for life. These were all discharged cases supposedly good enough to be at liberty. According to Dr. Wiley the normal average life was forty-four years; their records at Randall's Island showed the age of death among these feeble-minded to be thirteen years. Hence normal persons lived about three and one-half times as long as aments. The mortality tables showed that the death rate from pneumonia and inanition was very high, and that from diseases of the vascular system very low as compared with the normal rates. As to the financial side of the problem of the defective, the institutional cost of maintenance was about $200 per capita per annum. The cost of caring for the defective in the home would be as much, so that one might compute the cost of caring for 300,000 as $60,000,000 a year. In the Elmira Reformatory 37 per cent. of the criminals were found to be mental defectives, or more than one in every three. Greater New York's crime bill for 1906 was $35,000,000 and that of the nation $1,075,000,000. If one-third of these costs were charged to the mental defects of the criminals or to the neglect on

the part of the public, the cost of feeble-mindedness was very high. If the State could not segregate the feeble-minded it should sterilize them. There should be a law that no person in an institution at public charge, who had been properly adjudged defective, should be discharged therefrom without first being rendered unproductive. Children were not allowed to marry, so why should this class of individuals be allowed to do so when they were only children in intellect? Dr. Barr regarded a sexualization in the same light as quarentine measures, a protection for the public against disease. Earl Russell in England had said: "If the ruling classes in Parliament and in the law were composed of people of adequate medical knowledge, some such remedy as this would be the law of the land." Such were the views of many students of the subject and such were the author's views.

Dr. Charles L. Dana said that feeble-minded children were a menace to society and an expense to the State when they were dependent. They were a menace because of the danger of propagation. The question was how were they to be managed? The care of the feeble-minded should be placed under State regulation and the State should organize a State Board of Control similar to the State Board of Lunacy. Feeble-minded children should be cared for in the same way as were those mentally deficient. Such a State Board of Control should have a census taken and keep a Bureau of Records where the life history of these children might be kept. Before these children reached school age they should be cared for by their parents and after reaching the school age by the State. Dr. Dana thought it would be better to educate these children as far as possible under the direction of the Board of Education. When cases were found unfit for school work they should be referred to institutions. After these individuals passed the school age they should be cared for by the State under the supervision of the Board of Control and they should be placed in institutions provided for them. Some feeble-minded persons, not criminal, could be trained to become useful citizens. While such a plan was being worked up they would have to help get along as best they could with the agencies existing. The State Board of Charities had recognized the need of caring for the feeble-minded and were preparing to more than double the accommodations in the different State institutions. The ideal plan would be to have the child educated, cared for and looked after from the beginning of its life to the end, and treated merely as a person of unsound mind.

Dr. Charles H. Andrews of Buffalo said that they were all in favor of segregation of the mental defectives, but this was of no use under the law as interpreted by the Attorney-General. As soon as the child was able to do anything useful, he could be taken out of the institution at the request of the parents or grandparents. A boy who happened to be a firebug might destroy many buildings or a girl might become the prey of those who were looking for this class of girl. Dr. Andrews related one instance of a seventeen-year-old girl who was released at the request of her parents for a visit home, who during that short visit became pregnant by her own brother. This was but one of many instances which could be cited. What was the use of increasing the number of these institutions if the number of feeble-minded and criminals grew faster than the accommodations for them? Just what would be done in regard to sterilization in the State of New York was not yet known. The records and family histories of persons insane from hereditary causes would be examined and a history of the physical and mental condition of the individual would be noted and then, if the court approved, sterilization might be employed. Just how soon this would be done and to what extent remained to be determined and they were always willing to receive suggestions along these lines.

Dr. B. Sachs said that he did not believe that any great advances had been made toward the Utopian state by asexualization. It was well to adhere to the tangible phases of the discussion and he wished to say a word in regard to the higher defectives. There were always a large number of these slightly defective children. These children were not proper subjects for care on the part of the State. They were the unfortunate victims of unsanitary conditions. After more than thirty years of study he did not feel ready to give any conclusions as to whether these children were developed as the result of heredity or of environment. Much could be done by the relative, parents, and teachers in improving the mental condition of these slightly defective children. The environment of the family was a great factor, the general atmosphere in the home, discontent on the part of the mother, and preoccupation on that of the father, contributed much more to the development of defective children than assumed factors of hereditary origin. Dr. Sachs said that at times there had been a great cry against the schools, but that he wished to go on record as stating that there was no one power in force in any American community that tended so clearly toward the prevention of defective and nervous children as the healthy restraining influence of the average school. Fortunately for the defective child the schools were excellent places for discipline during his early life and this was the one force that appealed to him in the improvement of the child's condition. The Section on Pediatrics could exert an excellent influence by pointing out to the Board of Education the absolute necessity of having these slightly defective children cared for. The development of the normal child was interfered with when he was expected to pursue his studies in the same class with the abnormal child, and it was still a greater injustice to the abnormal child to be placed in the same class with the normal child. At present all the defective children in this city were in one class, which was ungraded, and this was a great error. Defective children differed from one another and special schools should be established with a series of ungraded classes. There was much good material among defective children and under proper training much could be done for them. The Board of Education of New York City should be urged to live up to the duty of training this class of higher defectives at least. The complete imbeciles and the seriously defective should be entrusted to the care of the State.

Dr. Max G. Schlapp said that Dr. Sachs was probably referring to the feeble-minded children when he said that a large percentage of them could be educated and become useful citizens. This statement was not borne out by facts. In looking over the reports of an institution where this kind of work was carried on he had found that a very small percentage of the feeble-minded were ever capable of doing any good work or of becoming self-supporting. The serious factor in the problem that was to be considered was the welfare of the members of the community. These children were without exception potential criminals. Most of them were sexual imbeciles. They were to be found in children's courts as well as in clinics. Time and again they would mislead the normal child. Dr. Schlapp differed with Dr. Stowell in the statement that feeble-mindedness was a condition and not a disease. Dr. Schlapp said he believed that feeble-mindedness was the result of such conditions as Basdow's disease, myxodema, Addison's disease, and similar conditions. If they considered these conditions as diseases then feeble-mindedness was also a disease. It was the duty of the State to take these feeble-minded individuals out of the community and place them in institutions where it might be possible to determine the nature of their condition and to get some prophylactic which would prevent its spreading or increase. Idiopathic feeble-mindedness was due to some disturbance of the internal secretions, although he could not say positively that this was the most important factor in the creation of feeble-mindedness.

Mr. Angus P. Thorne of the Department of Charities said that the most important thing was for the State to adopt some definite policy for the care of the feeble-minded and he believed that the State of New York was practically committed to a definite policy of segregation. At the present time the State Board of Charities had supervision over all institutions devoted to the care of the feeble-minded. He did not agree with Dr. Dana that a State Board of Control was necessary. The State Board of Charities had the power to do the work that was suggested for a State Board of Control. If the State would provide the means for caring for the feeble-minded, the State Board of Charities would handle the work. The most important thing was a scientific investigation to determine the underlying causes of feeble-mindedness. The Department of Charities had established a "Clearing House" for the examination of those defectives, and through the generosity of private citizens, had appointed a staff of physicians at Randall's Island who would study those admitted to the institution on the Island. Again the taxpayer was entitled to some consideration. There was no good reason why the city of New York should support feeble-minded persons in institutions when their relatives were well able to maintain them. He wished that they could get the cöoperation of all the agencies in the city and get them interested in the feeble-minded and he believed that they could then collect data which would be of value and would stimulate the authorities to make better provision for the care of feeble-minded children.

Miss Elizabeth E. Farrell, Inspector of the Ungraded Classes in the Department of Education of the City of New York, said that in this regard the school was not

doing a new work, but that it was simply adapting its instruction to meet the needs of the individual child. The school authorities had during the past twelve years promoted the idea of adequate institutional care for a large number of children in the schools who never could be self-supporting and who ought never to be allowed to take a place in highly organized city life. They felt that their work was one of demonstration only. As soon as the public understood that they had in the schools of the city children who would need supervision as long as they lived, they would have adequate room and some sort of legal provision for transferring them to farm colonies. They did not want the idiots in the schools, but they questioned the wisdom of those who would have them turn such children into the streets. They wanted the doctors to regard the schools as laboratories. They wanted to gather such records as would help in the understanding of the pitiful cases of psychoses that came to them for intelligent sympathy and help. They hoped that the time of arguing whether or not the defective child was really the concern of the public school had passed, but they would have to care for them until society realized its duty to itself and its obligations to the weak.

Mr. Hebbard, formerly Commissioner of Charities, said that it must be evident that the State could never segregate the 30,000 feeble-minded, imbecile, and idiotic that were within its borders. They should aim to care for the low-grade cases, the idiots, imbeciles, and low-grade feeble-minded. At the present time there were 6,000 of the 30,000 under public care, being paid for by the State or the various localities in the State. They ought to care for more than twice that number. They wished to help the Commissioner on Ellis Island in the examination of immigrants to make sure that no person of feeble mind should get into the country. He agreed with Dr. Dana that a person with a defective strain which was inherited was more dangerous to the country than one who was insane. The thing they needed most of all was the public spirit that would help institutions for the feeble-minded to get money enough to enlarge their facilities so that more defectives could be cared for. In the institutions devoted to the care of epileptics it was estimated that 98 per cent. of the inmates were feeble-minded. When one saw the forces at work to keep the feeble-minded child out of the State it seemed that they were making real progress. He did not think that a Board of Control, as advocated by Dr. Dana, was necessary or even desirable. They needed some changes in the law. It was sometimes easy to send these people to institutions, but it was difficult to keep them there. There was great need for an institution for delinquents and mental defectives; these persons should not be allowed to take up the room in reformatories. A mental defective could never be reformed. They should have large asylums in New York and in other large cities for the reception and study of these delinquents. This was a subject to which a body like the Section on Pediatrics could turn their attention with profit. There was much work along this line for the Board of Education and for the Department of Charities and they should work together in this matter. All good citizens should be ready and willing to aid in this work and then it would be done thoroughly and well.

Dr. L. Pierce Clark believed that the contention that Dr. Dana had made that these children did not have criminal potentialities was correct. An important issue was the economic one. A census should be made in the State by which the number and whereabouts of these feeble-minded children could be determined. Ten years ago it was estimated that there were from 2,000 to 3,000 feeble-minded children in the City of New York, but regarding these there seemed to be some doubt. It was now found that a fair estimate of the number was 6,000 or 7,000. Dr. S. Philip Goodhart believed that the most important class with which they had to deal was the atypical or high defectives. These children were most valuable to society as among them were those possessed of special aptitudes. Unless they were recognized early and trained properly they fell into the truly defective class. Their potentialities for development depended upon education and environment. Feeble-mindedness was a disease when it was dependent upon some lesion in the brain; it was always a condition in the sense of its affecting social and economic problems.

Dr. Stowell agreed with Dr. Dana regarding the care and need for guidance of these unfortunates. They must have persons with normal minds to direct them. He did not regard feeble-mindedness as a disease. The Board of Education should have charge of the education of both normal and feeble-minded children, but the feeble-minded should be in institutions.

## Therapeutic Hints.

**Drugs in the Treatment of Diabetes.**—Guthrie Rankin has obtained good results with the following combination:

℞ Extract of valerian,
Pure phenol, of each, 2 grains.
Codeine, 1/3 to 1 grain.
Extract of cascara, 1½ grains.

The valerian steadies the nervous system, the phenol disinfects the intestinal canal, the codeine controls the output of sugar, and the cascara provides for the daily evacuation of the bowel.—*British Medical Journal,* March 22, 1913.

**Stimulation of the Mammary Function.**—P. Rudaux, A. Grosse, and U. Le Lorier note that the best means of stimulating the secretion of milk is a mechanical one. The action of galactogogues is uncertain. The following may be tried:

℞ Aqueous extract of galega, 25 grams.
Glycerophosphate of sodium, 15 grams
Syrup of lemon, 500 grams

or

℞ Extract of white nettle, 100 grams.
Glycerophosphate of sodium, 10 grams.
Simple syrup, 500 grams.

Of either of the above there should be given four tablespoonfuls daily, administered in any beverage. —"Clinique et Therapeutique Obstétricales du Praticien."

**Inhalations of Ozone in the Treatment of Diabetes.**—D. Labbé and P. Pérochon state that they have cured or have greatly improved a certain number of cases of diabetes by means of this method of treatment. The inhalations are given in daily séances of fifteen minutes each. It is supposed that oxygen in the naissant condition re-establishes the equilibruim between the production and the consumption of sugar in the organism.—*La Presse Médicale,* March 22, 1913.

**Prescriptions for Anorexia.**—M. T. Schnirer presents the following as some of the favorite formulæ in the German and Austrian clinics:

℞ Tinct. amar. (Deutsches Arzneibuch) 30 grams.
Tinct. nucis vomicæ, 10 grams
M. et Sig. Twenty drops t.i.d., a.c.

℞ Tinct. cinchonæ,
Tinct. aurantii cort., āā, 10 grams.
M. et Sig. Ten to twenty drops t.i.d., a.c.

℞ Menthol,
Tinct. amar.,
Tinct. nuc. vom., āā, 5 grams.
Tinct. cinchonæ, 20 grams.
M. et Sig. Ten to fifteen drops, one hour before meals (Neusser).

℞ Tinct. rhei vin. (Deut. Arz.),
Tinct. arom (Deut. Arz.), āā, 25 grams.
M. et Sig. One teaspoonful t.i.d., a.c.
—"Taschenbuch der Therapie."

**For Infantile Colic.**—Leonard Williams gives the following prescription as recommended by Widerhofer:

℞ Tinct. cascarillæ, ♏x.
Tinct. krameriæ, ♏x.
Ol. anthemidis, ♏j-ij.
Syr. simplicis, ʒiiss.
Aquam, ad ʒii.

M. Sig.: One teaspoonful every two hours.—"Minor Maladies."

### WHAT IS PSYCHANALYSIS?

BY E. W. SCRIPTURE, Ph.D., M.D.,

NEW YORK.

ASSOCIATE IN PSYCHIATRY AT COLUMBIA UNIVERSITY.

ONE evening there came to Doctor Jung an elderly man in considerable excitement. He related that he had lately noticed that small sums were missing from his cash drawer. The police had been notified and the servants had been changed without result. It had just occurred to him that possibly a young man who was living with him might have taken the money. If so, he wanted to stop all further proceedings. He asked Doctor Jung to hypnotize the young man and inquire if he had committed the fault. Doctor Jung told him that this procedure would be hopeless, but that he had a method which would probably succeed.

The young man was brought to Jung, ostensibly for a consultation regarding his nerves. A set of words was prepared, including several that referred to the suspicious circumstances. These were mixed with about twice the number of indifferent words, the total being one hundred. The young man was instructed that when a word was called out he was to respond as quickly as possible with the first thing he thought of. The time was measured with a stop watch. Some of the results are given below.

| | | | | |
|---|---|---|---|---|
| 1 | Head | Nose | 2.0 | + |
| 2 | Green | Blue | 1.2 | + |
| | . | . | . | . |
| | . | . | . | . |
| | . | . | . | . |
| 12 | Give | Steal | 2.6 | + |
| | . | . | . | . |
| | . | . | . | . |
| | . | . | . | . |
| 19 | Burglar | Thief | 1.8 | + |
| 20 | Cook | ..... | ..... | ..... |
| | . | . | . | . |
| | . | . | . | . |
| | . | . | . | . |
| 46 | Right | Wrong | 2.2 | + |
| 47 | Thief | Burglar | 4.6 | Criminal |
| 48 | Find | Steal | 2.6 | Seek |
| 49 | Book | ..... | ..... | Law Book |
| 50 | Wrong | Right | 1.2 | + |

The first column gives the number of the experiment; the second gives the word spoken by the doctor: the third, what was associated by the patient: the fourth, the time it took him to respond. After going through the list once, the words were again called off; the patient was to repeat, if possible, the same word as before; otherwise he was to give the first thought that came to him. The fifth column contains a cross for a correct memory, and the new word for an incorrect one. The average time of response was 2.0 seconds.

We notice that the word "give" brought forth the word "steal." This in itself was unusual and suspicious; moreover, the time was much lengthened. After some indifferent results the word "burglar" brought forth the word "thief" very naturally in an ordinary time; but there was evidently so much disturbance aroused in the patient's mind that he could not associate at all to the following simple word "cook." Later the word "thief" brought the association "burglar" with the immensely long time of four and six-tenths seconds. The disturbance was so great that the patient forgot what he associated, and gave the different word "criminal" when he tried to remember it. The disturbance persisted so strongly that to the following word "fine" he associated "steal," taking a long time, and forgetting it; for the next word, "book," he was still so upset that he could not associate at all.

The result of one hundred associations was so convincing that Doctor Jung at once declared to the patient that he was a thief. The young man protested violently and asserted his innocence in great excitement. It was explained to him how he had betrayed himself in the experiments; thereupon he broke into tears and confessed.

Long experience has shown that whenever a word touches upon some topic in regard to which the person is sensitive, the records show one, or more, or all, of five different characteristics, namely: first, the time of response is lengthened; second, the first response is forgotten in the memory test; third, the association is likely to be superficial or trivial; fourth, there may be no association at all; fifth, the disturbance is likely to last over the next one or more experiments.

In the preceding case the disturbing events were known to and realized by the person himself. The method, however, is just as readily applied to cases where the person does not realize his condition.

Another case of Doctor Jung's was that of a happily married woman subject to explosions of jealousy with outbreaks of violence, and running away from the house. These outbreaks she carefully kept secret from the rest of the family; she wreaked her temper on her husband, who was a model man. In the association tests the strongest disturbances occurred with the words "happiness," "anxiety," "religion," "choose," "marry," "part," "death," "die." In her associations she used "like" thirteen times, "man" ten, "child" seven, "necessary" seven, "beautiful" six, "I" or "me" four.

It was possible to guess the story from these results alone, but it was easier to confront her with the record and show her that she had revealed conclusively that something was the matter with her happiness, that she was anxious about something, that religious questions were troubling her, etc. The patient agreed that she was not "happy" with her husband, that she was anxious about the future and did not know what to do, that she had "married" outside of her "religion" a man whom she "chose"

against the wishes of her parents, that she is debating if she shall "part" from him or "die." She also said that she "liked" "men," that a "child" is "necessary" for a happy marriage, that she ("I") is still "beautiful" enough to attract men. Further conversation showed that, although she had fitted herself to her husband, she was not satisfied with him, and that from time to time the feeling of resistance broke through. She would like to be loved by some other man; she had even telephoned to a young man to meet her in her husband's absence. She would be happy in any case if she had a child. The outbreaks of jealousy were projections of her own wishes; she would like to do the things with men which she accused him of doing with women.

A still more remarkable characteristic of the association test is the fact that the disturbance may occur when the test word touches upon the topics that have troubled us seriously in the past, but that have been so suppressed as to have been forgotten.

The fundamental fact of hysteria is that one or more disagreeable emotional experiences have been pushed out of the person's memory so that not only has he ceased to think of them, but also he cannot even remember them. These forgotten experiences affect, nevertheless, the results of the association test. The results enable us to draw definite conclusions as to what they are, and thus to get at the actual cause of the hysterical condition. I will not go into the matter of hysteria, but will turn to an illustration of this principle that I was able to furnish many years ago.

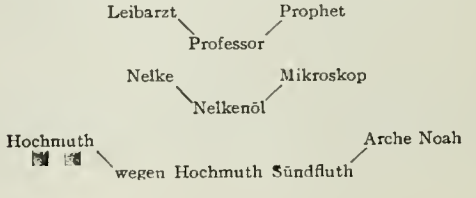
In 1895, that is, years before Freud had produced his theory of hysteria and Jung had devised his association experiment, I had published the results of investigations made in the Psychological Laboratory of Leipzig University, by which it was proved experimentally that an idea can be brought forth by an association through something of which the person is not conscious. Cards were prepared, each of which contained a picture in the middle and a small letter or character on one corner. Four or five such cards were flashed in succession on the ground glass of a camera-like apparatus. The time of exposure was made so short that, at the most, the subject was able to recognize only the picture without the small letter. Thereafter the small characters were exhibited alone, and the subject had to state which of the pictures first occurred to him. The following is a specimen series, the pictures being indicated by words.

| Peacock. | Shield. | Cat. | Flag. | Negro. |
|---|---|---|---|---|
| F | A | I | : : | C |

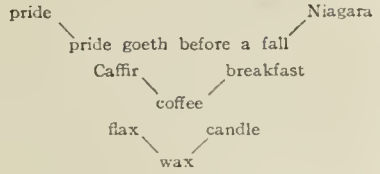
On one typical occasion when the small characters were shown alone without the pictures the results were I—cat, : :—flag, A—shield, C—negro, F—? Upon being questioned, the observer stated that he had not recognized any of the characters in the original series; he consequently had no reason to give for the associations, yet he had given all but one correctly. In all these cases the subject would feel that a certain picture belonged to a certain letter, although he had not seen the letter before as far as his knowldge went. From a number of experiments of this kind the conclusion was drawn that an idea which has not entered into the subject's full consciousness can be associated to an idea in consciousness, and can serve to reproduce it on a future occasion.

Further experiments were made by the following method: On one card there was a German word and some Japanese characters. On another card there was a strange word (Japanese, in Roman letters) with the same characters. A series of cards, comprising half of each kind, was shown in irregular order. For example, in one experiment, the following series (the Japanese characters being represented here by Greek letters) was shown in the order here given: (1) HANA α β, (2) HITO γ δ, (3) IUKU ε ξ, (4) KURU η θ, (5) MENSCH γ δ, (6) GEHEN ε ξ, (7) KOMMEN η θ, (8) BLUME α β. The subject was asked to state if he had noticed any associations between the first four words and the second four; he had not. Thereupon the words alone without the characters were shown him, with the request to state the first thing that entered his mind afer each. The results were as follows: (1) HITO—MENSCH, (2) KURU—KOMMEN, (3) HANA—? (4) IUKU—GEGEN, (5) KOMMEN—IUKU, (6) GEHEN—? (7) MENSCH—HITO, (8) BLUME—HANA. At the end the subject declared that all the associations were involuntary, that he could give no reason for any association, and that the Japanese characters had not occurred to him at all. Most of these associations were, nevertheless, correct; it seems probable that they were brought about by the influence of the Japanese characters which, nevertheless, had not entered into consciousness. This probability is increased by other experiments in which the word-association was correctly made and was followed by the occurrence of the characters. In still other cases the association was correctly formed without thought of the characters, whereas the subject could reproduce them when asked. Finally, the characters themselves were found to be in all stages of indefiniteness and forgetfulness, even in correct associations. It is to be remembered that all experiments were rejected in which any associations were made between the two parts of the series while they were being shown.

The problem was made the subject of further investigation by Aschaffenburg. In his experiments on the simple association of ideas a number of cases occurred in which the connection between the two ideas was intelligible only on the supposition of an intermediate idea. In the greatest number of cases this intermediate idea appeared to have been a sound-association with the inducing idea, while the relation of the induced idea to the intermediate one was of any kind. For example, to the word "Leibarzt" the person associated immediately "Prophet." A "Leibarzt" (a personal physician to some king or other important person) is in no way a prophet. He is, however, usually in Germany a professor at a university. The association "Leibarzt-Professor" is a natural one by similarity of meaning, and "Professor-Prophet" is also a natural one by similarity of sound. The quite irrational association "Leibarzt-Prophet" becomes rational if we assume the intermediate subconscious link "Professor." This case and two others may be represented as follows; the upper words give the conscious association, the lower word is the subconscious link:



Similar examples in English would be:



The intermediate idea in many cases does not remain completely unconscious, but appears as a following association. This shows that it was actually present in the mind at the time.

The association experiment of Doctor Jung is not the only method used in psychanalysis. Another method is the study of dreams.

In infancy we act freely according to our impulses, but from the very start we are trained to suppress them more and more. During sleep, however, our control is relaxed to some degree, and the suppressed impulses have a better opportunity to present themselves as dreams. This is exactly what dreams consist of, namely, representations of suppressed impulses. In the dreams of children these impulses are quite undisguised.

Freud relates that one night, after a day of fasting, he heard his little girl, nineteen months old, call out in her sleep, "Ann Feud, Erbeer, Hochbeer, Eicrpeis, Pap." It was quite evident that in her dreams she was satisfying her hunger by the various articles that she liked.

My niece, eight years old, had received a present of some Bantam chickens; she was rather disappointed at their smallness and at the fact that they could not be expected to grow larger. The next morning she related in great glee that she had dreamed she possessed a number of big Cochin China chickens. She had owned some Cochin China chickens the preceding summer. The incidents of the dream were furnished by events of the preceding day (owning the Bantams), and of a time not long before (the Cochin Chinas). The incidents of the dream are called its "manifest content." The study of thousands of dreams has established as a first principle that the manifest content is derived mainly from events of the day before or of a recent time.

Why should the little girl have a dream substituting large chickens for small ones? Her pleasure the next morning gives us the answer. The Bantams disappointed her; she would have preferred Cochin Chinas, that is, she really wished for them, although she probably did not recognize that she had a wish. This wish had not been fulfilled in reality, the dream fulfilled it. The study of thousands of dreams establishes the fact that they are made up of realization of wishes that have not been fulfilled in reality.

The fact of the wish does not appear to the dreamer. He does not dream that he is wishing something, but that he has it. The wish is an element deduced from the incidents of the dream. Such elements established by deduction belong to what is called the "latent content" of the dream.

With older persons the dreams are not so simple. We are taught more and more from infancy through childhood that we must regulate not only our acts but also our thoughts. Certain topics we must not permit ourselves even to think about. For example, we must not speak about our bodily functions, we must be careful that they are not observed by other persons, and we must not think about them unnecessarily.

Sexual topics are not so mildly suppressed. We must not talk about them. We must keep them secret, and in most cases we must not even think about them. We are taught to view many of them with horror. And yet they are just as natural as the instincts of hunger and the bodily functions; they are just as firmly implanted in us as in any of the animals. In the animals they have free expression; with us they are violently suppressed.

What is the result? In our dreams they strive to show themselves. The dreams of children and many dreams of adults are frankly sexual. But the suppression is usually so vigorous that our natural desires are not permitted to show themselves disguised even in dreams. There is, however, a way out. If our suppressed desires can so disguise themselves that they do not shock us, then they can often succeed in presenting themselves to us. This is the origin of the symbolism in dreams.

The habit of symbolism being once established, it is applied constantly and often quite unnecessarily in dreams. I will give a few illustrations of such dreams.

A patient relates a dream of a large white figure, which is an advertisement for a well-known breakfast food. He ridicules it. The figure becomes very angry. He retreats in fear, and finds himself on a snowy ridge. The figure blows a strong blast of snowflakes after him. He is accompanied by his three children. He sends two of them toward the valley to hunt for help. He and the other child try to get shelter behind some trees. The snow falls too rapidly and he decides that they will all stick together. He therefore calls back the two children, saying that they will all get shelter on the other side of the ridge. They climb up, sometimes over their heads in snow, and finally get over into safety.

To analyze a dream we first ask what has occurred recently that has suggested items in the dream. On the day before the dream the patient had been much interested in the decision in a libel case involving a weekly magazine and a food manufacturer, arising from an alleged fraudulent claim by the latter for some of his breakfast foods. He was particularly satisfied with the verdict for various reasons, and thought it was good punishment for the manufacturer. These were the suggestions that brought up in the dream the thought of the breakfast food and the ridiculing of the figure. When asked why the figure should have become angry, he said he at once thought that if he should express his delight at the decision it might offend possible customers who were in sympathy with the manufacturer. When asked if anything had lately occurred regarding snow or mountain climbing, he said that on the day before he had seen in a window an advertisement of the snow slides in Switzerland, and had been very much interested in them. They had brought him back to a previous visit to Switzerland. The ridge in the dream resembled a ridge which he had climbed the preceding summer, with the three children that appeared in the dream. Another factor that might have suggested the winter scene was the fact that he had been awakened by the coldness in the room in which he was sleeping. When asked if the blast of snowflakes suggested anything, he said that he had recently been very much worried about his financial situation. He had felt that he was being "snowed under" by difficulties that he had encountered. The incident of the children represented almost exactly what he had done a few months before. Getting to the other side of the ridge suggested the fact that he had recently decided to add

a new line of business in order to obtain more income. Getting through the snow suggested not only the financial difficulties, but also a scene in "Wuthering Heights," which he had just read. These recent events and thoughts had furnished the matter that made up the manifest content of the dream.

But why should he have had this dream? In other words, what was the latent content that had produced the dream? What were the impulses that sought to express themselves through the symbols?

They are always of two kinds, namely, wishes or fears. The first thought, which was very apparent, was his fierce desire to fight all humbugs. This was one of the most fundamental traits of his character. The second was naturally the wish to get out of his financial difficulties by a new line of action. The third was the wish to have his family together.

Dreams represent the working out of unfinished problems. These were exactly the problems that were worrying the man. He had not solved them in reality, but he solved them satisfactorily in the dream. In this case there was no necessity for symbolism. He might just as well have represented the facts otherwise, but the symbolic habit was a fundamental one and was used even when unnecessary.

Psychanalysis is thus a group of methods used for analyzing the human mind, particularly those portions of it that are not directly conscious. It is quite analogous to the work of dissecting the body and the microscopic study of the tissues. It is careful, cautious, and exact, and is a worthy complement to the scientifically accurate anatomical and physiological neurology of the present day.

236 West Seventy-fourth Street.

## GASTRALGIA NERVOSA AND ITS DIFFERENTIAL DIAGNOSIS.

By JACOB GUTMAN, M.D.,

BROOKLYN, N. Y.

During the past decade the study of gastro-intestinal diseases has received considerable attention from various investigators: pathologists, physiological chemists, and clinicians. Many problems relating to the chemistry of digestion have been satisfactorily solved, the pathology of a number of previously indefinite diseases has been better defined, and the diagnosis of many pathological conditions has been so much simplified, that we are enabled to recognize them to-day with nearly mathematical accuracy.

A great deal of credit for the extraordinary progress made in this branch of medicine, particularly gastrology, is due to the successful labors of the radiologists, especially Rieder, Holtzknecht, Albers-Schoenberg, Haudeck, and Schwartz. Thanks to their studies the exact location of the stomach, its size, form, mobility, functional activity, or other characteristics are with but slight efforts like an open book to every medical man. Thus his burden has been lightened considerably; while formerly he had to base his diagnosis or exercise his therapy relying upon subjective, oftentimes unreliable symptoms of the patient, the physician is now enabled to dispense with the latter, but make his diagnosis with practically perfect certainty, depending upon scientific principles and his own observations only. The reason we now obtain therapeutically so much better results is because treatment is more rationally applied. We are also enabled to correct surgically many conditions in their earlier stages when a cure is possible, while previously we were compelled to wait for their further development until their diagnosis could be sufficiently established, when perhaps surgical operation would already be impractical or impossible.

Of the numerous ailments of the stomach the diagnosis of carcinomata, ulcerations, pyloric obstruction, and similar pathological changes of the stomach wall has especially been favored by the investigations and the latest advances in radiology. But one class of stomach affections seems to have received but little attention, the neuroses. The study of these diseases, rather common in the practice of every practitioner, seems to have been neglected, and the literature thereon is comparatively meager; even the latest text-books merely give a classification with perhaps a most superficial description of a few of them, thus creating an impression of rarity or unimportance. Yet a thorough understanding of these diseases is essential; we do not know how soon we may be called to the bedside of a patient suffering with intense abdominal pains, vomiting, cold sweats, small pulse, pallor or other symptoms of collapse, necessitating an immediate and exact diagnosis. A wrong diagnosis may unnecessarily send such a case to the operating table with perhaps the diagnosis of a perforated ulcer, cholelithiasis, or acute intestinal obstruction, instead of gastralgia, as has been observed by the writer upon several occasions. But besides being important, the neuroses are not infrequent; out of two thousand cases of stomach affections Friedenwald found 1952, or 79.6 per cent, were functional neuroses and gastralgia nervosa constituted no small percentage of these. It seems probable if the numerous cases of gastralgia occurring in private practice were identified and not mistaken for diseases of similar symptomatology their percentage would be considerably increased.

Because of the frequency and importance of these diseases it is the object of the writer to recall the subject of gastralgia, adding his personal experience and particularly his instructive observations made in the hospital division of Prof. Gustav Singer, at Vienna, desiring at the same time to acknowledge his indebtedness to the latter for the numerous courtesies shown him and for the wealth of material placed at his disposal.

By gastralgia nervosa we understand certain acute paroxysmal, more or less severe attacks of pain in the stomach region with the characteristics of neuralgias in general. The stomach is endowed with three functions: secretion, motion, and sensation. Its functional activity depends mainly upon the stimulation it receives through the terminal filaments of the vagosympatheticus. The latter is concerned with the vegetative processes of life. It supplies all the organs containing smooth muscle fibers, most of the secretory glands, and a number of organs with striated muscle fibers, such as the heart, terminals of the esophagus, rectum, etc. Hence there exists a common carrier of impulses for all these anatomically closely related systems of organs, a close union between the cardiovascular and glandular systems on the one side and the gastrointestinal and genitourinary systems on the other. It is also easy to comprehend how the impulses may be at times misdirected and assert themselves in organs rather distant from the real seat

of irritation, not in immediate proximity of the causative factor. The vagus is of great length, being the longest cranial nerve of the organism, and before reaching its final distribution it comes in touch with a great number of organs. This relationship is of importance; the nerves may be subjected to irritation of pressure from inflammatory changes, displacements, or new growths of these organs, producing either an exaggeration or a diminution of the normal stimulation of the gastric mucosa. This explains why a change may occur in the quantity or quality of secretion because of some psychic effect in the one case, while in another an attack of gastralgia will result because of irritation of some distant organ; it also explains why the gastrointestinal tract plays in general such an important part in the symptomatology of other diseases.

As far back as 1876 Leube, in his description of the stomach neuroses, divided them in accordance with the character of functional disturbance into three groups, and each of the groups into two subdivisions: an *irritative*, characterized by an overactivity of a particular function, and a *depressive*—indicated by diminished activity as compared with the normal. Accordingly, we have depressive forms of neurotic diseases (achylia, atony, hypesthesia) and irritative groups (hypersecretion, hyperkinesis, hyperesthesia), depending upon the type of perverted stimulation. The gastralgias under consideration belong to the latter class, the irritative form.

In accordance with the above stated definition, before we may pronounce an attack of pain in the stomach region as gastralgia nervosa it must comply with three conditions: (1) the pains must be located or originate in the stomach; (2) they must be of neuralgic character; (3) the stomach wall must anatomically be free from lesions.

In explanation of these requirements let it be remembered that other organs may normally or abnormally be situated in the epigastric region, in the usual position of the stomach, and thus be the real seat of pain, while the latter may be wholly innocent of the attack. The latest studies with Roentgen rays have conclusively demonstrated the variable localization of the stomach and its change of relationship to the other abdominal organs, even in the same individual or in the same day. Thus pain in the epigastrium may sometimes be outside of the stomach in another organ.

Besides, every "pain in the stomach," as the popular expression goes, is not necessarily a neuralgiform attack. The characteristics of pain are different: we should not mistake the colicky pains of pylorostenosis, the burning pains of hyperacidity, or the extreme tenderness of the overstretched Glissonian capsule of an acutely congested liver for neuralgic pains. They are not true neuralgias, even if appearing in paroxysms; they have none of the qualifications of the latter as will be seen later.

The third requirement is the exclusion of direct pathological changes of the stomach wall; otherwise, the gastralgia should not be classed as of nervous origin. In spite of the many methods at our command this is not always a simple proposition, and we still oftentimes fall into error in our diagnoses. In some cases notwithstanding the diseased state of the stomach wall, the patient does not subjectively seem to suffer and the stomach thus escapes our attention, while in others our attention may be distracted by the associated diseases of other organs of the individual. At the autopsies of a number of cases deceased from destruction of other organs the writer has seen ulcers of the stomach, young carcinomata, and considerable constrictions of the pylorus, which would be expected to give some signs of their existence, and yet the individuals during life seemed free from any disturbances indicative of such pathological changes. We must therefore be careful before we speak with certainty of nonexistence of anatomical changes in cases of gastralgia.

It is understood that gastralgia nervosa is a neurosis of the vagus, similar to neuroses of other sensory nerves in other parts of the body. Certain irritations of these nerves are supposed to result in neuralgia pains; irritation of the vagus may result in neuralgia of the stomach or gastralgia. Owing to the close relationship, anatomical and topical, of the vago-sympathetic with a great many organs, the irritations may be derived from many sources, most of which may be definitely located, but in a percentage of cases a demonstrable cause seems impossible to be determined; the latter are classed as the so-called *primary* or idiopathic class of gastralgia nervosa, while those having a definite reflex origin are considered as *secondary* or reflex gastralgias.

But in either variety there are three factors which are instrumental in provoking an attack of gastralgia. In the first place, there is almost always an unusual susceptibility of the patient's nervous system; it is oversensitive and too responsive to external influences. We find it among those with a neurotic family history (hysteria, neurasthenia, hypochondriasis), or the complainant himself may have been in the past a sufferer from nervous derangement. He is often an irritable, easily excitable individual, complaining of headaches, vertigo, insomnia, periods of hypochondria, etc. His reflexes are unusually increased, his sympathetic highly irritable, and may exhibit a fine tremor. Eppinger and Hess have rightfully placed these individuals in a class by themselves, the vagotonics. They are unique and are easily differentiated from the other types. The tone of their sympathetic system is different from the normal, responds in an exaggerated manner to external and internal stimuli by drugs, and is highly strung, ready to respond upon the slightest provocation. It is met more frequently among females, whose nervous system is already highly sensitive, and at those periods of life when it is especially responsive and prone to derangements—puberty, the menstrual periods, the early months of pregnancy, and the menopause. At the latter time, the period of reorganization of the woman's organism and its adaptation to its new phase of life, gastralgia is not an infrequent companion of the other unpleasant symptoms, the result of the disturbed equilibrium of her internal secretions.

The nervous predisposition plays a no less important rôle in man than in woman, but seems due to other causes and met at an age when most subject to the effect of our strenuous life. Business worries, continuous irritations, the rush and busy whirl of city life, late suppers, insufficient and irregular sleep, and in addition, the abuse of alcohol, tobacco, and venery, suffice to change even a rugged constitution into that of a nervous, debilitated, and irritable individual.

Frequent as we find the above mentioned factors among the higher classes of society, the poorer classes are equally great sufferers from an unstable nervous system. It has been the experience of the writer to attend a great many gastrointestinal cases

among the tenement population in New York, and to find a great percentage of these to be of nervous origin. The members of the tailoring trade of New York, in addition to frequent catarrhs, anorexia, constipation, and other gastrointestinal disturbances of pathological origin, seem to be particularly predisposed to the neuroses. Perhaps their mode of living, hard sweatshop work, hurried meals, short noonday rest, and bent posture at the working table may be contributory factors to the predisposition.

The second and next important factor in the etiology of gastralgias is the irritation of remote organs terminating in attacks upon the stomach. The genitourinary system plays proportionately an important rôle and the frequency of uterine disturbances in females seems to be another reason why they are more subject to the diseases under discussion. Malpositions of the uterus, especially retropositions, chronically inflamed adnexa, perimetritis, pelvic adhesions—are some of these causes, while a gravid uterus is often an obstinate one. Nephroptosis is the cause of a great many abdominal pains and is frequently a factor of gastralgia, which subsides upon the reposition of the organ to its place and its retention there.

Of the abdominal organs, the gall-bladder and ducts are frequent contributors to reflex gastralgias, while the appendix is even of more importance: if chronically inflamed and matted with the other tubular organs, it may constitute a good cause for a very obstinate case of gastralgia to be relieved only by operative intervention. Patterson has but lately again called the attention to the appendix, suggesting a careful examination of the latter in every dubious case of gastralgia. At least one such case has come lately to the attention of the author. A high official of the country suffered for a number of years from frequent paroxysmal attacks of gastralgia. Notwithstanding the many therapeutic measures used by his attendants to relieve the various attacks he was not getting any permanent relief. An intervening sudden acute attack diagnosed as appendicitis necessitated an immediate operation and the removal of the organ. Since that time his gastralgias have ceased and have never returned; their cause, the appendix, has been removed.

Hernias, external and internal, figure in the etiology of gastralgias. The small easily overlooked pea or bean-shaped protuberances in the median line above the umbilicus, tender upon pressure and oftentimes simulating painful points of an ulcer, may be the origin of violent attacks. Peritoneal adhesions, simple or tuberculous, perigastritis, intestinal coils adhering to the abdominal wall may also result in similar attacks.

The nervous system plays no negligible part in the etiology. Besides the gastralgiform pains common in most spinal diseases, true gastralgias are associated with locomotor ataxia, multiple sclerosis, syringomyelia, and the functional disturbances, hysteria, melancholia, etc. In tabes dorsalis gastralgia is an early symptom and often the first to call attention to this disease; in other degenerative conditions it may occur later in the disease and is not so characteristic as the classical "crise gastrique."

Hysteria and neurasthenia are very frequently associated with neuralgiform pains in various organs of the body. In hysteria these may be its only manifestation. The former may assert itself in the form of gastralgia only and be limited to the stomach in the same manner as it may limit itself to any of the other organs; paralysis of a limb, paralysis of the larynx with resulting aphonia, affection of the eye-muscles with consequent strabismus, etc. This is particularly true of the primary idiopathic cases, where no cause seems demonstrable and yet through very careful examination the association with a number of definite stigmata of hysteria, the latter can be diagnosticated. With "neurasthenias" the gastralgias are even more frequently associated than with hysteria.

To the blood intoxications producing typical attacks belongs tuberculosis. It is quite usual to meet even advanced cases in which the patient complains only of anorexia, achylia, or other symptoms of gastrointestinal catarrh, seemingly the only disturbing effects of the circulating toxins. In some cases the toxemia asserts itself in the form of typical gastralgias. An explanation is wanting; perhaps local irritation of the vagus terminal filaments in the diseased area of the lung may be the factor of transmitting the expression to the stomach endings. It is important to keep tuberculosis in mind especially if there are some symptoms suggestive of this disease.

Other blood intoxications causing gastralgias are malaria, arteriosclerosis, gouty diathesis, alcoholism, nicotinism, mercury, and lead. The last named is the most frequent of all of them. Even mild intoxications with lead are often accompanied by the severest attacks of gastralgia. Extreme anemia and chlorosis are also productive of attacks.

The third factor concerned in the induction of an attack is some immediate incident, which seems to call forth the attack proper. This is usually some psychic moment: a fit of anger, mental emotion, aggravation, psychic trauma, and is particularly influential in the primary idiopathic cases.

The onset of an attack is oftentimes preceded by premonitory symptoms, but these are not essential. If present, they usually consist of a tired feeling, indisposition for mental work, dull headaches, vertigo, drowsiness, fullness in the throat (globus), nervous eructations, etc. The attack proper begins with sharp, boring or lancinating pains, beginning at some point in the epigastrium and radiating backward to the spine and shoulders, seldom downward. The onset is independent of food inbibition appearing on one occasion before a meal, at another—after or between meals; it is independent of the kind of food and of the time or hour of the day. They are paroxysmal in nature and of variable duration, from a few minutes to an hour or more. During the attacks the patient is often found in an upright posture with his clenched fists pressing tightly against the abdomen, thus looking for relief. His face is pale, the skin cold and moist, his look anxious, his pupils dilated, his nose pinched, the pulse small and irregular, respiration shallow; the patient seems very weak or may be completely collapsed. During or after an attack he is taken with vertigo, nausea and vomiting and passes frequently large quantities of light-colored urine of low specific gravity (urina spastica).

The intervals between individual attacks are of various duration, irregular and characterized by freedom from any complaints. The patient seems in good health, has good appetite, good digestion, and is of usual disposition. The irregularity of the attacks, of their severity, of the intervals, and of their origin are characteristics of the disease.

But not in every case do we find the above described complex of symptoms with all its prominent features so characteristic of gastralgia; on the contrary, in a great number we have no such typical attacks, but milder and of a modified symptomatology. Some of the enumerated symptoms may predominate while others may be absent or remain in the background. These are the milder forms and the harder cases to differentiate from other diseases with similar suggestive symptoms. They are oftentimes mistaken for colics, indigestion, gall-stones, heart trouble, etc.

Because of the similarity of symptoms of the pathologically less serious diseases of gastralgia nervosa with those of a number of very serious diseases, the differentiation of the latter from the former may at times present a difficult problem. Mistaking a case of gastralgia for graver conditions (perforation of an ulcer, peritonitis, cholelithiasis, appendicitis) may not be followed by such serious consequences to the patient as diagnosticating the latter for the former; it may become very serious or even fatal. It is unusual though to diagnose the serious pathological diseases as gastralgia; on the contrary, we often assign the pains of gastralgia to an ulcer, gallstone colic, appendicitis, and other conditions, especially if transient. It is not unusual for surgeons to make a laparatomy for supposed ulcers of the stomach, gallstones, appendicitis, etc., to find upon opening the abdomen nothing unusual; later these cases prove to be nothing but pure neuroses. The writer has but recently witnessed such a case in the surgical division of the above mentioned hospital. The operation was undertaken for supposed gastric ulcer. Upon opening the abdomen the stomach, gall-bladder, and all other organs of the locality were carefully inspected but found perfectly normal. No cause seemed on hand for the gastralgiform attacks, the hypersecretion, and other symptoms simulating ulceration of the stomach. Thanks to the appearance of slight bladder disturbances and paresthesias of the soles of the feet several months after the operation, the attention was soon directed to the nervous system and the case was soon identified as a true tabes. Mistakes in diagnosis are frequent and usually due to poor attention or little consideration given to the gastralgias when confronted with an attack of colic in the stomach region. Let us, therefore, consider the most common diseases coming into consideration, when confronted with such an attack as described under symptomatology.

Cholelithiasis, cholecystitis, choledocystitis, etc., habitats of a nearby organ, may be ushered in with similar prodromal symptoms and present conditions similar to those of gastralgia. In the early stages when icterus is still absent, or in those cases where icterus is altogether wanting throughout the attack, the differentiation may present some difficulty. The history may relate of some previous similar attack with jaundice in a gall-bladder case, while in gastralgia the history will be that of a neurotic. The pains in the former begin at about the position of the bladder, at the intersection of the right costal border with the outer border of the rectus muscle and radiate more to the right of the median line, while in the latter the pains are felt to the left side of the median line and radiate toward left. Tenderness always absent in gastralgias, is usually found over the area of an engorged liver and its overstretched capsule; it is aggravated by pressure, while in gastralgias the contrary, pressure is more gratifying to the patient and gives him relief. Oftentimes a tumor of the obstructed and overfilled gall bladder may be felt in cholelithiasis, in gastralgias—none. The urine of gastralgia patients is passed frequently in considerable amounts, is of light color, low specific gravity and contains no abnormal constituents; in hepatic cases—it is of lesser quantity, dark, foamy, of high specific gravity, contains bile, urobilinogen, urobilin, an excess of indican, scatol, etc. The feces are also abnormal and may contain biliary stones, be light colored, fatty, pasty, etc. The intervals are not free from gastrointestinal symptoms in gall-bladder cases, while in gastralgias they usually are. If elevation of temperature or jaundice appear then the diagnosis is so much more simplified in favor of liver affections.

Left renal or ureteral colics should next be taken into consideration. The differential diagnosis may not be as difficult as in the above conditions. The difference in the chemical composition and the microscopical picture of the urine is so absolute as to enable one to make the diagnosis from the examination of this fluid alone. In kidney cases the urine is passed at short intervals with evident strangury, but in small quantities, because of the oliguria. It is of high specific gravity, strongly colored, sanguinous and may be loaded with uric acid crystals, urates, oxalates, phosphates in addition to hyaline casts, blood corpuscles and leucocytes. In gastralgia the urinary secretion is also frequently passed but is light colored, voluminous, of low specific gravity, and contains none of the above mentioned pathological constituents. The pain is located more in the lumbar or ureteral regions, which may be quite tender to pressure, radiates downward toward the loins to terminate in the meatus urinarius in the male or the labia minora in the female; in gastralgias such irradiation or termination is never present. Neither are backaches so common in the intervals of gastralgias as in nephrolithiasis. The etiology may also be characteristically different in the one case from the other; in nephrolithiasis an attack may result from some violent exertion (riding, jumping, running, horseback), a gastralgic attack would be induced by some unusual psychic shock. In some cases, with a meager panniculus the stone may be definitely located by a Roentgen examination and thus the diagnosis established beyond doubt.

Acute intestinal obstruction may have to be taken into consideration in differential diagnosis. The onset of intestinal cases is usually not so acute, but this should not be much relied upon, as gastralgias may also have a gradual onset; the symptoms are of more importance, some even pathognomonic. The "facies abdominalis," the difficulty in breathing with an immovable diaphragm, the fetor ex ore, the frequent eructation of foul smelling gases, the hiccough, the continued vomiting, first biliary later stercoracious are symptoms accompanying intestinal obstruction and never gastralgia. Besides, possible palpation of a sausage-shaped abdominal tumor, the oftentimes visible or easily felt peristalsis above the place of obstruction, the considerable meteorism, the obstinate constipation, the retention of flatus, the scantiness of the urine loaded with fermentation products, etc., will suffice to exclude gastralgia in favor of intestinal obstruction. In fact, the pictures of these two conditions when de-

veloped are so different that a separation presents no difficulty; only in its early stages it may give some trouble to do so.

Intestinal colic if severe as met with in the fermentation diarrheas, tubercular or non-tubercular bowel ulceration, may also be mistaken for gastralgias. This is especially true when complicated with gastroptosis, when the normal position of the stomach may be occupied by the greatly distended intestines, the place of the attack. We differentiate these cases from true gastralgias by the qualifications of the evacuations (extreme costiveness, unusual diarrheas), the presence of considerable bowel distension by the rumbling and gurgling sounds, periodicity of the pains, by the relief produced after the passage of the flatus, by the absence of vomiting, of severe collapse, by the scanty urine, excess of coloring matter, indican, scatol, etc. The abdomen is tender to the touch and in thin walled individuals the peristaltic movements of the intestines may even become visible. There are no globus, urina spastica or other manifestations of nervous gastralgia.

Pancreatitis acuta, sialolithiasis, embolism, and hemorrhagic infraction of the pancreas are very infrequent factors, but in differential diagnosis have still to be given attention. In the above conditions the symptoms appear acutely resembling the onset of gastralgia. They usually are of a severe type, are located in the left hypochondriac region and accompanied by severe nausea and vomiting soon terminating in collapse. In some cases death results so soon that it is practically impossible to attempt to make a correct diagnosis. In the more chronic and less severe forms we may differentiate the same from gastralgias by the characteristic voluminous, adhesive pancreatic stools, loaded with all varieties of fats especially neutral, by the presence of undigested muscle fibers with retained nuclei, often undigested starches. The stools must be examined after a day or two of a special diet, such as Schmidt's. The presence of sugar in the urine or alimentary glycosuria will also point to the pancreas as the source of the trouble. If we have accompanying the above symptoms jaundice, which results from pressure by an enlarged head of the organ, as in new growths, or symptoms of portal obstruction (dropsy, enlargement of the liver, enlarged spleen, gastrointestinal catarrh) from outside pressure by enlarged glands upon the portal vein, then the diagnosis becomes more simple.

But in one form of pains of pancreatic origin which are hardly accompanied by definite pancreatic symptoms, the diagnosis is extremely difficult and usually made at the autopsy. This form is extremely dangerous and may terminate by sudden death, as in the case Zenker relates. These are the so-called "neuralgiæ cœliacæ" and are supposed to be provoked by some sudden pressure of the pancreatic substance upon the sympathetic plexus, with which it is in such close relationship anatomically and topically. Luckily these cases are not frequent.

Another disease to be considered is angina pectoris. It is well known how different may be the character and how various are the directions into which the extremely acute pains of this disease may take situation, from the usual course along the distribution of the ulnaris to the rare neuralgiform pains of the testicle. This extensive irradiation is explained by the anatomical arborization of the vago-sympatheticus. In that form of angina pectoris described by Neusser, "the typus abdominalis," in which the pains are localized in the abdomen, the symptoms may resemble gastralgia in every detail and it is then possible to mistake the two. It is of particular importance to think of this possibility when considering the prognosis of a case: the latter may terminate fatally, while the gastralgia need not menace life. It is, therefore, advisable to be on guard when determining the prognosis of an attack of gastralgiform pains in an elderly person (or a younger person with syphilitic history) with sclerotic changes in the arteries, high tension pulse without kidney involvement, etc., unless we can surely exclude angina pectoris. In the rest of the cases the feeling of oppression or tightness of the chest, brady- or tachycardia, irregular heart rhythm, sensation of terror or impending death, the usual radiation of the pains to the two inner fingers of the left hand, or physical symptoms of myodegeneratio cordis will suffice to exclude gastralgia from true angina pectoris.

Intercostal neuralgia, left sided, has several symptoms in common with gastralgia nervosa. In intercostal neuralgia the pain radiates in the direction of the ribs, is more superficial and oftentimes accompanied by herpes zoster along the course of the nerve affected or its branches. Nor are the pains as severe as those of gastralgia and do not produce collapse. A careful examination will enable the exclusion of this condition without much difficulty, especially if all other symptoms characteristic of gastralgia are taken into consideration.

Having thus excluded diseases with similar symptomatology of organs other than the stomach, let us now consider affections of the latter coming under the same heading. There are a number of stomach disturbances which are accompanied by pains of greater or lesser severity (catarrhs, hyperacidity, acute indigestion, bulimia), but the pains have a different character and very little in common with the typical gastralgia attacks, thus coming hardly into consideration under this heading.

It seems unnecessary to state, that in every case of gastralgia it is essential to give the patient the most scrupulous examination: (1) in order to exclude anatomical lesions of the stomach wall; (2) to exclude the possibility of other organs being diseased and being the seat of pains, and (3) for the purpose of discovering the presence of remote causes instrumental in induction of the attack reflexly. The first is the most important reason why full attention should be given to the stomach itself: a careful history, careful inspection, palpation, auscultation, or inflation may reveal sufficient evidence perhaps to make further investigation unnecessary. But a stomach examination without a chemical analysis of its contents, and without a radiologic examination after the usual bismuth meal is an incomplete one; that latter test will often reveal conditions which may greatly surprise the examiner. Even if the state of the stomach has been sufficiently determined by physical examination to the thorough satisfaction of the physician, it is still advisable to employ the chemical and radiological tests for verification and additional proof of his previous findings. Such examination may soon enough indicate whether or not the neuralgiform pains are due to direct stomach lesions, as gastric ulcer, pyloric obstruction, pylorospasms or not.

In stomach ulcers, attacks if present will have some connection with the ingestion of food, in

gastralgia nervosa the onset is independent of it. Nor are the intervals in ulcerative conditions altogether free from disturbances; they are also shorter and periodically more regular. In addition we have more definite symptoms of an ulcer to be guided by: a clean red tongue, sour eructation, heartburn, pain in the epigastrium, often depending upon the patient's posture, tenderness aggravated upon pressure, sanguinous vomiting or bloody feces in occult cases, tender nerve points along the spine, etc.—all symptoms unusual to gastralgia nervosa. Some of the therapeutic tests may also be employed for verification; a dose of bicarbonate of sodium administered during an attack may terminate the same if due to ulcer, neutralizing the hyperacidity, while in gastralgia—the alkali will have little or no effect; on the contrary, the administration of a teaspoonful of cognac with pepper, as recommended by Chvosteck, will considerably increase the pain of a gastric ulcer, while in gastralgia it often affords immediate relief. The electric current may also be employed in these cases for diagnostic purposes, applied inside or outside the stomach the galvanic current will give immediate relief if the attack be of nervous origin. Generally speaking, the difficulty of differentiating these two diseases in most cases is not very great, although in certain individual cases it may be extremely difficult and even impossible. This is particularly true of duodenal ulcerations, whose symptomatology is shy of many of the above enumerated symptoms. In such cases we have to rely mainly upon the presence of blood in the stools and in addition upon the more or less constant localization of the pain to a definite point of the abdomen, its appearance, usually 4-6 hours after meals, its dependency upon the variety of food ingested and the presence with gastrointestinal disturbances between attacks. But in spite of it all, there are still a number of cases, except duodenal, in which even the most careful examination, including Roentgen rays, fails to reveal the presence of an ulcer, and yet there is one indolently lurking somewhere in the folds of the gastric mucosa, as its future course may show. Therefore Riedel and Leube have advised in every case of so-called idiopathic gastralgia, where anatomical lesions seem impossible to be located the case should still be considered as one due to ulcer, and the patient placed upon an ulcer diet, closely observing for some time its effect upon the future course of the attacks.

Concerning the recognition of the oftentimes pronounced pains accompanying obstruction of the pyloric orifice of the stomach (from within or without) and their differentiation from gastralgias, it may be said, that they are usually of a lesser degree of severity and appear shortly after the ingestion of food and at short intervals (5-15 minutes). Most every painful cramp is accompanied by rumbling sounds, the liquid chyme forcing itself through the narrowed opening, while the peristaltic and antiperistaltic motions of the stomach wall are very frequently observed through the abdominal walls of some individuals. As a rule these patients are emaciated either as a result of imperfect digestion and inanition, or because of the original disease, the cause of obstruction; besides, the stomach musculature is also hypertrophied; another factor which helps to make the peristalsis visible. At times the pyloric end may be palpated through the abdominal wall. In addition, stenosis is most always accompanied by gastrectasia with the lower curvature of the stomach, perhaps at or several fingers below the umbilicus, with periodical vomiting of large amounts of ill-smelling liquid containing a multitude of sarcinæ, yeasts, and other products of fermentation, with its feeling of distention, fullness, dragging down pains, which are unusual with gastralgia nervosa, and thus speaking in favor of obstruction.

Acute peritonitis may in its early stages because of its acute onset, severity of pains, nausea, vomiting and collapse be confounded with an attack of gastralgia. Later the symptoms develop so differently that to mistake one for the other seems inexcusable; the tenderness and rigidity of the abdominal wall, the vomiting, obstinate constipation, considerable meteorism, syngultus, the characteristic posture in bed, the indicanuria—reveal the true cause of the pain and soon dispel any remaining doubt as to diagnosis.

*Secondary reflex gastralgias.*—Having excluded the possible involvement of the other organs in a case of neuralgic pains in the upper abdomen, and having thus decided that we have before us a case of true gastralgia nervosa, the next necessary step is to endeavor to locate the cause of the attack. From a therapeutic standpoint it is imperative, as we have no particular special treatment of the disease, and the cure depends entirely upon the correction of the underlying cause. In order to locate the latter it is necessary to examine all those organs, which may cause reflexly such attacks, as enumerated under pathology. In females a gynecological examination should never be neglected whether subjective complaints are present or not. The examination may oftentimes disclose conditions, which are more than sufficient to induce such attacks. Neither should the appendix be slighted in the examination, a rectal examination should be a matter of routine. Hernias must be investigated for, but here is where we may be led astray: it is not difficult to diagnose hernias when able to palpate them, but when confronted with intraabdominal varieties, the case may become very perplexing. Treitz's duodeno-jejunal hernias, hernia diaphragmatica, bursæ omentalis, subcœcalis, etc., are nearly inaccessible to diagnosis, but may produce all kinds of symptoms, including severe gastralgias; they may be suspected though in some cases when other causes are excluded, by the localization of the origin of the attacks, the constancy of this position, the gastrointestinal disturbances, constipation, distention of the bowels, but often positively diagnosed by repeated radiographic examinations at various intervals after the intake of bismuth.

Hernias of the median line are easily excluded if proper thought is given to it. They appear in the forms of buttons or small nodules, are tender upon pressure, feel hard or lobulated, and the skin covering it is freely movable. They consist of protruded portions of preperitoneal tissue, omental fat (lipoids), and rarely even stomach wall.

Tabes dorsalis of which the gastralgic pains or "crises gastrique" in the preatactic stage are the earliest manifestations, must always be borne in mind, and other early symptoms of the disease, such as loss of Achilles tendon reflexes, paresthesias, pin point, or Argyll-Robertson pupils, positive Wassermann should be looked for. If present, they constitute sufficient indication to begin definite antiluetic treatment, staving off thereby further progress of the disease, the degenerative processes, for a number of years and thus making the patient's

life so much more comfortable for the time to come. If the gastralgias appear in the latter stages when the degenerative symptoms are already distinct, the diagnosis of the cause then presents no difficulty. The same is true with the other nervous diseases, with which abdominal pains are common; multiple sclerosis, syringomyelia, myelitis. They all have to be diagnosed by associated symptoms, common to these diseases. The gastralgic attacks occurring with hysteria, neurasthenia, and melancholia are not infrequent and are recognized by symptoms and stigmata of the disease, which are so well known, that a repetition seems unnecessary. The attacks in these cases are often very stubborn, resist all rational treatment, and are characterized by relapses following the slightest functional or psychic disturbances.

This brings us finally to the blood intoxications conducive to gastralgias. In malarial poisoning the attacks occur in periodical order with chills, fever, and sweats as the other manifestations of this disease. The locality may lead to malaria as a clue, while if melanin or the plasmodium is found in the blood the diagnosis is certain. In doubtful cases a course of quinine may help to decide.

Gastralgia in the course of *anemia, chlorosis* may be diagnosed by the characteristic blood picture of the respective disease or symptoms of the same: oligocythemia, polychromatophilia, anisocytosis, the hemoglobin index, normoblasts, etc.

The recognition of tuberculous intoxication as the cause of the attack is of unquestionable importance. It occurs usually in that stage of the disease, the initial stage, when lung symptoms may be extremely indefinite, but when proper attention will give the patient enormous benefit. If suspected, a most searching examination of the lungs, glands, abdomen should be made, the sensitiveness of the cervical plexus tested, Kroenigs' and Williams' symptoms looked for, an *x*-ray plate made, or tuberculin injected as a test. The absence or presence of definite evidence will substantiate or reject the suspicion of tuberculosis as a cause.

Of the poisonings lead occupies by far the leading position as a factor in the etiology and thus should first receive our attention in differential diagnosis. It is rather remarkable how some individuals are peculiarly susceptible to the effects of lead and become intoxicated if exposed to it even slightly or coming in contact but for a short period of time. It had been the opportunity of the author to attend to several of the severest gastralgic attacks following short or seemingly insignificant exposures to lead poisoning. The latter may be recognized only when other symptoms common to this disease are present: basophilic granulations of the erythrocytes (very typical), anemia, constipation, high tension pulse, paresis radialis or wrist drop, arthralgias, etc.

Arsenical or mercurial poisonings must also be remembered. They are recognized only by the symptoms typical of these poisonings, as the neuralgic attacks have of themselves nothing characteristic.

Finally, after our efforts to locate definitely the place of irritation or origin of the gastralgic attack were unsuccessful we may come to the conclusion that the case under consideration is of idiopathic origin. But this decision has to be accepted very cautiously and not until every effort has been made and all means exhausted to exclude every possible organic cause as a factor, and even then we must still bear in mind, that a number of just such cases have some underlying cause which we are unable to disclose, as the number of true idiopathic cases is comparatively small.

## THE ALBUMIN ANALYSIS OF THE SPUTUM.

### ITS GREAT VALUE AS A RELIABLE AND POSITIVE DIAGNOSTIC LABORATORY METHOD FOR DIFFERENTIATING PULMONARY TUBERCULOSIS FROM OTHER PULMONARY DISEASES.

By JOHN RITTER, M.D.,

CHICAGO.

ASSISTANT PROFESSOR IN MEDICINE, RUSH MEDICAL COLLEGE

From the days of Laënnec to the present time, the examination of the chest, either for the study of the normal conditions of the intrathoracic organs, or for the interpretation of the various pathological changes in the chest cavity, has been usually by means of the physical methods. Of all the diseases of the chest that of the lungs has always claimed the physician's closest attention, and particularly has this attention been directed to the interpretation of the physical phenomenon, as is observed in pulmonary tuberculosis. By the physical means now at his command the internist finds but little difficulty in pointing out definitely the condition of the diseased lung, and its extent of involvement in the moderately advanced and far advanced cases of pulmonary tuberculosis, different in the early incipient stages of the disease when there is still good hope of effecting a cure or, at least, an arrest of the tuberculous process. In beginning tuberculosis when the lesion is still very small an examination of the chest, by physical methods, will not always give us a true picture of the pathological conditions of the underlying lung tissue, and we are oftentimes forced to try to arrive at some definite conclusion by means of other methods, and especially is this true in the stage of pre-incipiency, termed by L. Landouzy "Bacillary Stage," that a positive or, at least, a relatively positive diagnosis would be most desired.

Diagnostically tuberculin may be used to indicate in a limited number the beginning tuberculous process in the lungs; however, in the greater number of cases of pre-incipient phthisis the use of tuberculin is not sufficiently distinctive nor positive, and while the radiograph may be of definite service in advanced tuberculosis, it also will not aid us very much in making a diagnosis of beginning infection. It is in this very incipient stage of tuberculous infection that a physical examination combined with laboratory methods will often aid us to arrive at positive conclusions, hence, laboratory diagnosis should be applied in every case of suspected pulmonary tuberculosis. It will accord in many cases with the clinical picture enabling us to make a definite diagnosis when the physical signs are still very meager. The examination of the sputum is, next to that of the blood, of the utmost importance. Not a microscopic examination to determine the presence of the tubercle bacillus, for, if bacilli are already in the expectorations the case has in all probability long passed its stage of incipiency, but a chemical analysis of the sputum showing the presence or absence of albumin. In recent years our attention has been directed to this special phase of laboratory

diagnosis, and in particular have European clinicians, chiefly French physicians, given it much interest and attention, and they have done an enormous amount of work in this direction. Among the first and original in this line of investigation are the labors of Roger et Levy-Valenci.[1] They reported the sputum examinations of a total of 1,200 cases of positive tuberculosis as represented by the three stages of the disease and the chemical analysis of the sputum nearly always gave an albumin positive reaction (negative in only seventeen samples). Lessieur[2] states correctly that all sputa containing the bacillus of Koch, demonstrated by direct microscopic examination will invariably give a positive albumin reaction, but if the sputa give a negative albumin test the presence of the tubercle bacillus can not be shown by either direct microscopic methods or by any other method, and that the albumin reaction is usually absent in those affections which do not invade the bronchopulmonary parenchyma but is present, persistent and constantly, in the course of all pneumonias, caseous broncho-pneumonias also often positive in cardio-renal disease. In 190 observations the albumin reaction was positive in 100 per cent. with bacilli in the sputum and the diagnosis of pulmonary involvement demonstrable. According to Rodriguez Alves[3] the albumin reaction exists in all the various phases of the disease and is always present at every stage, incipient or advanced and Roger[1] concludes that the sputum of the tuberculous is invariably albuminous, hence the absence of albumin from the sputum always permits the elimination of suspected tuberculosis, but the presence of albumin does not always allow the positive assertion that a suspected patient is suffering from pulmonary tuberculosis because albumin is found in the sputum of individuals suffering from other than lung affection; it is, however, significant that a negative albumin content is positively non-tuberculous. An interesting contribution by A. Delhage[4] is worthy of note. He found the reaction negative in 71 cases of acute bronchitis, in 14 cases of chronic bronchitis with emphysema, in two cases of whooping cough and in one case of pneumonoconiosis; positive in all cases of pneumonia, bronchopneumonia, pulmonary gangrene, pulmonary stasis and in 78 cases of pulmonary tuberculosis, second and third stages, and equally positive in 24 out of 48 cases of suspected tuberculosis incipiens. He concludes from these findings that the albumin reaction indicates a pulmonary change within the parenchyma, an activity, that neither the tuberculin reaction, neither auscultation or percussion nor radiography is capable of differentiating from an inactivity. Lecalplain[5] states that in all forms of progressive pulmonary tuberculosis, immaterial in which stage it may be classed, the albumin reaction is always positive, that if the sputum is constantly albuminous without the Koch's bacillus being present, a repeated and diligent search should be made; finally the bacilli will also be found.

L. Guinard's[6] contribution is also very interesting. He vary carefully reviews the labors of his pupil, Smolizanski, confirming the observations of Roger. Smolizanski made 255 sputa analyses at the Sanitarium at Bligny. Incipient or first stage cases, 40; moderately advanced or second stage cases, 104, and far advanced or third stage, 111. Thirty-three of the 40 incipient cases were positive and seven negative; 103 out of 104 moderately advanced cases were positive, only one negative, and the 11 far advanced cases all positive, and he concludes that the negative reactions show that the expectorations indicate the disease arrested or that the foci were at the time latent or inactive but that in all forms of an active process the albumin reaction was diagnostically positive. Geeraerd[7] states that the albumin reaction if not of specific value is nevertheless a sign of great importance which in all cases in which the cutaneous reaction is positive indicates a tuberculous involvement.

The sputa of 108 suspected tuberculous patients presenting themselves for examination were first carefully collected, then chemically tested for albumin. As all were ambulatory cases, the different samples of sputa were from individuals representing all stages of pulmonary tuberculosis, from infectious and from non-infectious, as well as from non-tuberculous, from bronchitic asthmatic and congestive. The chemical analysis showed that 33 patients were non-tuberculous, the sputa being entirely free from albumin, and of the remaining 75 all gave a more or less positive albumin reaction, 10 giving a reaction indicating a mere trace. These different albumin reactions, according to the amount of precipitated albumin shown in the test tube when a ferrocyanide solution was added, were all placed into three arbitrary groups. A light albumin precipitate was usually designated as belonging to group X, the one showing a massive, heavy or dense precipitate was placed in the 3X group and an intermediate albumin sediment into group 2X; accordingly 23 belonged to group X, 19 to group 3X and 23 to 2X. In 30 of this series of 65, microscopically the sputum showed unmistakably the presence of the tubercle bacillus and the association of the bacillus and albumin in the same sample of sputum was always positive. Every sputum examination showing microscopically the presence of the Koch's bacillus gave a positive albumin reaction, but not every sample of sputa giving the chemical reaction for albumin determined the presence of the tubercle bacillus, nor did the amount of albumin present give any possible indication as to the number of bacilli present. One sample of sputa of this series giving an albumin reaction sufficient only to be placed in group X, as well as one sample from the 10 indicating a mere trace, gave a microscopic picture of many bacilli in each field, while on the other hand a few of the series which indicated chemically a massive albumin content showed only a few or an occasional bacillus in a given field, hence neither from a massive albumin content of the sputum can we infer the presence of tubercle bacilli in the microscopic picture, nor can we conclude or estimate from a stained specimen with any degree of accuracy, with either few or many bacilli in the field, the probable intensity of the albumin reaction. The statement made by Ch. Lesieur[2] that a massive albumin content is usually more serious, as the tubercle bacilli are then usually more numerous or abundant, has not been corroborated in this series. Now the remaining 35 examinations of this series, all of which gave a positive albumin reaction without the tubercle bacilli being present, were grouped with the former 8 belonging to 3X, 11 to 2X and 16 classed as X. The physical findings of the first or 3X group, 8 in all, were all positive and all reacted to the tuberculin test. Of group 2X the physical findings

were fairly positive in 6 and negative in the other 5. The sputum of 2 of the latter was that from young individuals who were reared in a tuberculous home, in the family of each only recently a death occurred from pulmonary tuberculosis, and out of 8 of the X group the physical findings were only in a measure positive and negative in the remaining 8. An analysis of the sputa of the 10 cases giving an albumin reaction indicated by a mere trace, one showed positive pulmonary findings with laryngeal complications, and the sputum gave a microscopic picture with many bacilli in each field, chiefly in clumps, and in 6 the diagnosis of incipient pulmonary tuberculosis was only fairly well made from the physical signs, the remaining three were most likely negative.

In summarizing the results of the chemical sputa analysis of these 108 samples we glean the following facts: 33 sputa samples were free from albumin and 75 were albuminous. In 10 albumin was present as a mere trace of which one showed many bacilli in the microscopic field; 19 showed a massive albumin content of which 11 were bacilli positive and 8 bacilli negative; 23 moderately albuminous, 12 being bacilli positive and 11 bacilli negative and 23 simply albuminous with 7 bacilli positive and 16 bacilli negative or 31 bacilli positive with albumin in varying amounts and 44 albumin positive but bacilli negative. The 33 samples of tested sputa with negative albumin findings must be classed as sputa obtained from positively non-tuberculous individuals; 31 albumin positive sputa were also tubercle bacilli positive showing that the sputa was that from patients undoubtedly tuberculous, the remaining 44 samples although albumin positive were bacilli negative but for that fact should not be classed as non-tuberculous sputa. In the case of one-half or 22 of the latter, albumin positive and bacilli negative samples, a fairly accurate diagnosis was made by physical examination corroborating the albumin analysis and in the remaining 22 albumin positive only a tentative diagnosis could be made and it is most probable that with repeated examinations and the use of tuberculin many, even with negative physical findings, will be placed in the positive class. In this connection it may be of interest here to note that in 5 samples of sputa showing by chemical test the presence of albumin, but, no Koch's bacillus found even after a careful search over more than 30 field in each, that after injecting a milligram of tuberculin, intracutaneously, followed by a positive reaction, a second sputum examination gave approximately the same albumin content as in the first, but in addition the microscopic field now revealed many bacilli.

The chemical analysis of the sputum of the tuberculous or suspected tuberculous is deserving of a much wider and more practical application than it is now receiving on account of its simplicity, its precision and its easy applicability, above all because of its determined negative value, and from the convincing results obtained we must conclude that in sputum examination we are dealing with a method which should be classed with the most accurate of the various diagnostic means. It is of especial value in those cases of pre-incipiency when the clinical picture is not at all positive, the case is still closed, non-infectious, the bacilli are usually not present at this early stage it is then that the albumin reaction may point to a distinct positive tuberculous involvement for the absence of albumin from the sputum is always negative for tuberculosis. Every case of suspected pulmonary infection should therefore receive, first, a thorough and careful clinical examination, next, if needed, a diagnostic intradermal tuberculin application and last an accurate chemical sputum analysis and the paramount importance of the last can not be too vigorously emphasized.

*The importance of properly collecting the sputa.*—A proper way for collecting sputa is most essential to the correct interpretation of the albumin reaction. The patient must be instructed to cough up deep from the lungs, usually in the early morning, the first on rising, and place the sputum into a clean sterile bottle and securely close it with a well fitting cork stopper. He must be specifically instructed not to collect the secretions from the mouth, buccal cavity, nasopharynx or from the throat but only such as he can bring up from the bronchial tubes, for this alone is suitable for making a reliable albumin test. To wash out the mouth or gargle with a few mouthfuls of warm water will usually clear the mouth and throat from all adherent secretions after which the sputum should be collected. A properly collected specimen should be examined at once, in any event, it must not be more than about 6 hours old, in cold weather an expectorated sample will keep for 24 hours before undergoing fermentative changes. Only the freshly collected sputum should be tested, decomposed secretions will often give a reaction simulating albumin. No antiseptic solution or any preservative agent should be added before making the albumin test.

*Directions for making the sputum test.*—As the technique is so simple, the results so satisfactory, and the necessary apparatus so few the examination of the sputum should become a routine method in the case of every suspected or positive tuberculous. Put 5 c.c. of sputum into a glass cylinder of about 25 c.c. capacity (glass cylinder must be supplied with a well fitting ground glass stopper), add 5 c.c. of distilled water and about 10 drops to 1 c.c. of glacial acetic acid, replace the stopper, shake well, and set aside. Shake occasionally during the next 20 or 30 minutes, then proceed to filter. If the sputum is suitable for filtration it will have separated into three distinct layers reminding one very much of an expressed stomach content ready for testing. Should the middle or watery portion of the sputum solution be still a little opaque, showing the presence of some remaining unprecipitated mucin add a few drops more of the glacial acetic acid, again shake well and set aside as before. The fluid portion now appearing clear, proceed to filter it through a plain wetted filter and test the clear filtrate for albumin in the usual way by either Heller's test or the heat test, both of which are very satisfactory, but at my hands the ferrocyanide test has proven the most reliable and accurate. If to an albuminous solution of sputum in a test tube a drop of 10 per cent. ferrocyanide of potassium solution is added, an approximate idea of the amount of albumin can at once be gathered by observing the drop of ferrocyanide solution carrying down the precipitated albumin and one can also notice the difference between a massive albumin content and one in which only a small amount of albumin is present by the manner in which the precipitated albumin falls to the bottom.

*Conclusions.*—1. If the chemical examination of the sputum is albumin positive but tubercle bacilli negative with physical findings obscure and

indistinct, the intradermal injection of tuberculin will often change both to positive.

2. A positive albumin reaction and a positive tuberculin test are of far more importance diagnostically than the negative clinical examination, also the negative value of the albumin and the tuberculin tests are of far greater, of more positive, value than the negative clinical examination, because, a negative clinical diagnosis may still be doubtful, may not be positively negative.

3. A single positive sputum finding can not be considered positively and diagnostically tuberculous but a single negative albumin reaction can assuredly be considered as non-tuberculous.

4. A negative sputum for albumin is also microscopically negative for the tubercle bacilli; usually with the open or infectious cases both albumin and bacilli will be found in the sputum, while, in the closed or non-infectious cases albumin minus the bacilli will be present.

5. The positive albumin reaction is a sure indication of an inflammatory invasion of the pulmonary parenchyma which may be tuberculous, pneumonic or congestive, and the reaction is always negative when the inflammatory process has not affected the substance of the lung as in acute and chronic bronchitis and asthma, hence the reaction is of most importance in those cases in which the pulmonary infection is not yet manifest and the differential diagnosis lies between tuberculosis and simple bronchial catarrh.

6. Albumin in the sputum is often the forerunner of the tubercle bacillus and albumin may be found in the sputum many months before the bacilli make their presence known, hence a positive sputum content with but meager or very slight physical findings and negative bacilli favors a possible incipient or pre-incipient tuberculous diagnosis, and

7. Like all clinical signs it must be considered with all the other signs, including both subjective and objective, to arrive at positive conclusions.

## EPILEPSY.*

By C. R. M'KINNISS, M.D.

NORRISTOWN, PA.

As it would be impossible in one brief paper to cover the entire subject of epilepsy, we shall confine out time to the etiology and some of the mental phenomena of epileptics.

This disease is one of the oldest to which man is heir, and we find early descriptions of it by Hippocrates, who contended against the popular belief of his day that it is a disease inflicted by the Gods and said the only reason for ascribing a divine origin to it, is because its nature is incomprehensible. The epileptic paroxysms he believed due to a struggle between the humors and the pneuma (or breath) in the vessels. He was also a firm believer in hereditary transmission of the disease. Lucretius, in his poem, "De Rerum Natura," refers to "the fermenting humors" as the cause of the convulsions in his classical description of the Grand Mal seizure:

"Oft, too, some wretch, before our startled sight,
Struck as with lightning, by some keen disease
Drops sudden: By the dread attack o'erpowered
He foams, he groans, he trembles and he faints;
Now rigid, now convulsed, his laboring lungs
Heave quick, and quivers each exhausted limb.
Spread thro' the frame, so deep the dire disease
Perturbs his spirit: as the briny main
Foams thro' each wave beneath the tempest's ire,
He groans since every member smarts with pain
And from his inmost breast, with wontless toil
Confused and harsh articulating springs.
He raves since soul and spirit are alike
Disturbed throughout, and severed each from each
each
As urged above distracted by the bane.
But when at length the morbid cause declines,
And the fermenting humors from the heart
Flow back—with staggering feet first treads,
Led gradual on to intellect and strength."

Among the more recent authorities Spratling defines epilepsy as " a disease or disorder affecting the brain, characterized by recurrent paroxysms which are abrupt in appearance, variable in duration but generally short, and in which there is impairment or loss of motor co-ordination, with or without convulsions."

Turner says, "Epilepsy is a chronic progressive disease of the brain, characterized by the periodic occurrence of seizures, in which loss of consciousness is an essential feature; commonly associated with convulsions, and frequently accompanied by psychial phenomena of a well defined type; occurring generally in persons with a hereditary neuropathic history, which shows itself in signs, or stigmata of degeneration; running its course uninterruptedly, or with remissions, over a number of years, and terminating either in a cure, in the establishment of the confirmed disease, in delusional insanity or dementia."

Epilepsy is the "morbus sacer" or sacred disease of several centuries before the Christian era, so called because certain priests were presumed to be in epileptic seizures just prior to making their prophecies; it is "the priestly disease" of the Greek, and a priest who was subject to epileptic seizures was thought to possess a higher order of sanctity. It is the falling sickness, spells or fits of to-day, and the poor, unfortunate subject is kept in the background of the family circle, his school life limited, he learns no trade and is frequently made to feel that he is out of place among his fellow men.

We no longer attribute the cause of epilepsy to the benevolent interest of mythological deities, to vapors and humors arising in the body, nor the possession by devils. Most pathologists will admit that there has been no lesion found in a sufficient number of the various forms of epilepsy to consider it to be the cause. Certain changes in the nervous

*Read before the Montgomery County Medical Society.

system, as a cortical gliosis with chromatolysis of the cortical cells, blood changes and changes in certain glands have been observed, but what relation they bear to the disease cannot at this time be positively known, some writers claiming these changes to be the etiological factors, while others of equal authority advocate opposite views.

Possibly the most satisfactory work is being done along the line of abnormal metabolism—observation made on the blood, urine, sweat, and gastric juices immediately preceding and following a convulsion have shown a condition of hypertoxicity, though in the interval this has been found much reduced or normal. Uric acid has been claimed as the cause of the seizure (Haig), the carbamate of ammonium (Krainsky) has also been mentioned, while Donath has suggested cholin, a substance found in the spinal fluid, as the cause, but this has also been obtained from paretics and senile dements. Ceni mentions cytotoxin as the cause, but none have shown conclusive proofs. The convulsions of some epileptics appear more like the discharge of an accumulating cause than a constant pathological change in the nerve cells, and during the interval between seizures many epileptics appear like normal persons. That the seizures are due to an accumulation of some toxic substance in the body is further indicated by the symptoms common to epileptics, as drowsiness, headache and faulty elimination; in some cases the existing gross brain changes account for the epilepsy, but even in these some other factor may play a part in causing the paroxysm. We also meet with similar convulsions in uremia, lead poisoning and chronic alcoholism, which we look upon as being due to the presence of toxic matter in the system. And the more we see of the so-called "epileptiform" convulsions observed in these diseases and in sclerosis of the cerebral vessels and hear of senile and alcoholic epilepsy the more we are inclined to think that the present conception of epilepsy will in time cease to exist. With further knowledge of brain lesions and autointoxications the greater number of cases of epilepsy will be reclassified and the name idiopathic epilepsy will be discarded.

A causative factor of epilepsy with which we must reckon is that abnormal state of the nervous system, which stimulated by some exciting cause inaugurates the seizures, and to some extent the first seizure acts as a factor in inducing those that follow, forming an epileptic habit, as it were.

As to predisposing causes, heredity, in this as in many other diseases, leads the van, and in the study of epilepsy we are forcibly reminded that "like begets like." Spratling found in a series of 1,070 epileptics (660 made and 410 female) that 17 per cent. had epileptic parents, and this direct inheritance seemed slightly more marked in female epileptics. In the same series he combined the inherited influences, epilepsy, insanity, alcoholism, tuberculosis and other diseases, and found that 56 per cent. were included. He found alcoholism in the parent a cause in 16 per cent. of the male and 12 per cent. of the female epileptics. In 7 per cent. of the male and 10 per cent. of the female epileptics insanity in the family was found. Gowers in a study of 2,222 epileptics found heredity to play a part of 40 per cent.

The average age at time of onset is from 9 to 10 years, and when epilepsy appears after 30 years of age it strongly suggests cerebral changes due to syphilis. One author (Fore) claims that epilepsy is more frequent in females, though what statistics we have seen show the opposite sex to be more often affected (20:16 Spratling).

Reflex causes, such as eyestrain, adenoids, nasal polypi, hypertrophied turbinates, intestinal worms and tight prepuce have been mentioned, and by causing a constant irritation on an already abnormal nervous organization they undoubtedly must be considered, though many epileptics have had their eye condition corrected, the polypi, turbinates and prepuces removed, dosed with santonin and quassia to remove the intestinal inhabitants, but still the seizures continue. Spratling states that in studying 1,800 epileptics "he is unable to recall a case in which he felt the whole cause to lie in any anomalous condition of the visual apparatus," while Stevens, Ranney, and Gould claim eyestrain to be a prominent cause of epilepsy.

Epileptic seizures occur most frequently during sleep, and Pick has called attention to their frequency during deep sleep, that is immediately after falling asleep and an hour or two before waking, at a time when the maximum of brain anemia is present. Clark explains their occurrence during sleep by the lessened inhibitory control, while Haig believes it to be due to the variations in the reaction of the blood.

The mental state of epileptics varies within wide limits, and we may find many symptoms which characterize other psychoses. The epileptic character is in most cases distinctive, though changeable. Grasset sums it up as follows: "On the one hand they are somber, tacitturn, defiant, suspicious, always ready to fly into a passion, to hurt people, to become enraged and to strike; on the other hand, they are contrary, obsequious, obliging, wheedlesome, full of effusion and gentleness. In reality epileptics are all or nearly all irritable, subject to attacks of sudden, violent, and ferocious transports of rage during which time they do not, as it were, belong to themselves. This irritability is the keynote of their character. Many have in addition vice and perverse instincts. Many are greedy and violent. They frequently have a tendency to a sickly piety or a sort of excessive religiousness, mixed with hypocrisy."

Some epileptics go through life having a variable number of seizures, and outside of their mental dullness following a convulsion they are apparently normal persons. The mental symptoms bear no fixed relation to the type, severity or frequency of the convulsions, and several cases have been recorded in which no definite convulsions were observed, yet they manifested profound disturbances. By some authors the periodic alcoholic indulgence known as dipsomania is claimed to be epileptic in nature.

The usual terminal state of the epileptic is dementia: he becomes in the end a mere vegetating organism, but in noting the exception to this rule Sir Lauder Brunton (1901) says, "It is quite true that some of the most remarkable men in the world's history have been epileptics, but I do not think that Julius Cæsar, Napoleon or Mohammed were great because they were epileptics. As a rule epilepsy tends to destroy mental power rather than to increase it, and the curious lethargy which Napoleon exhibited at the battle of Leipzig and which there led to his defeat and consequent ruin is probably rather to be ascribed to his epileptic tendency than to the indigestible bun which is said to have led to

the disaster. Julius Cæsar and Napoleon were great men not because of their epilepsy, but in spite of it. And the visions of Mohammed alone would not have given him the extraordinary power over his countrymen and over the then known world had it not been backed up by extraordinary mental power in the interval between the fits."

We might add that Ann Lee (1758) who became the leader of the Shakers and brought a colony of that sect to America must have possessed other powers than her epileptic visions and the belief that she was inspired and the woman alluded to in Revelations (Chapter XII, 1st and 5th verses), "A great wonder appeared in heaven; a woman clothed with the sun, and the moon under her feet, and upon her head a crown of twelve stars. And she brought forth a man child who was to rule all nations with a rod of iron; and her child was caught up unto God and to his throne."

The common symptoms we observe when interviewing an epileptic are some impairment of memory, abundant conceit and self-assurance. Their religious fervor is often strongly contrasted by their conduct. We have known them to consign us to hell with many adjectives and even threaten personal violence because they were not permitted to shout during chapel service. They frequently read their Bible and carry it about with them, refer to the life to come, in which they will be free from the "sickness." Many of the great religious movements are said to have been initiated by the ideas and ecstasy accompanying epileptic seizures. Mahommed was an epileptic, according to Moreau. Swedenborg was probably an epileptic, and Ann Lee had grand mal attacks with some hysterical symptoms.

Dr. James C. Howden inquires how far epilepsy has had to do with the origin of certain religious creeds and how far the visions of many so-called religious impostors may have had an epileptic origin, and of Mahommed he says, "It seems incredible that a religion which sways the minds of 200,000,000 of the human race at the present day should have no better foundation than the visions and dreams of an epileptic."

During the preparoxysmal state an epileptic may show mild excitement or mania, melancholia with rare suicidal attempts; some have a feeling of impending personal harm, some have impulses to do strange things, though frequently following the convulsion the mental atmosphere is cleared. The following case shows the abnormal impulse with lack of insight into the seriousness of the act at the time:

Case I.—White male, 57 years of age, was admitted to an institution with the following history: Since 17 years of age he had been employed as a clerk by the Pennsylvania Railroad. He had been subject to epileptic convulsions (grand mal and petit mal) from 5 years of age, following a fall. At 35 years of age a trephine operation was done with some temporary relief. At intervals he had attacks of frenzy, when he threatened various members of his family, but never made a homicidal attack. A few days before his admission, without warning, he procured a revolver, fired twice at a neighbor, and for about two hours he was dull and confused, not realizing the seriousness of the act. After his admission it was learned that the neighbor had sold him some real estate and the patient thought he had been cheated, though at the time of the shooting he could give no reason for it.

Occasionally postparoxysmal disturbances occur, varying in type and length of time they persist.

The stuporous type usually follow severe convulsions or *status epilepticus* and in which they show profound physical and mental lethargy. They are aroused with much difficulty and all reflexes are diminished or lost, muscular twitching may be present as residuals of the storm that has passed. As they regain consciousness poorly defined hallucinations or delusions may be expressed.

The maniacal type usually follow grand mal seizures and is characterized by extreme frenzy, the patient blindly assaults anyone about him, consciousness is partially or completely obliterated during the attack, to such an extent that he has no knowledge of it afterwards. Fortunately these dangerous periods are brief, and this is the most dangerous phase of the epileptic psychoses. Let me mention a case to emphasize this point.

Case II.—Male, white, 36 years; farmer, admitted to an institution. He had epileptic seizures since 15 years of age, due to head injury. This man had frequent postparoxysmal attacks of frenzy, during which he attacked members of his family and neighbors. Before his admission to the hospital he had been dull and confused for two days, then he had a grand mal seizure, following which he became maniacal, drove his family from the house, attacked a neighbor who was passing; he was profane and abusive, and after being overpowered he was placed in jail and later committed to the hospital. After remaining four months with us, during which time he had few convulsions, he was permitted to leave the hospital with his wife, though against the advice of the physicians. After one month he was returned in handcuffs and with many discolorations from bruises. There was the same history of homicidal attacks without provocation. He remained irritable and excitable for five days, reacting to vivid aural and visual hallucinations, expressing many delusions of a persecutory nature. After remaining in the hospital a few months he had a series of convulsions, with intervals of noisy irritability, and died from exhaustion.

Epileptics do have maniacal attacks not associated with any convulsions and which has been spoken of as psychic epilepsy or a psychic equivalent, lasting from a few minutes to a few days, and in this they differ from acute mania, which is of longer duration. The intensity of the epileptic's maniacal fury is a feature. At times they pass into a state of automatism in which they talk, eat and perform certain acts of which they later have no knowledge. Cases have been reported while in this state to have made railway journeys and to commit crimes. The following case may be cited:

Case III.—Male, colored, 27 years, laborer, no education, one maternal uncle insane, one sister feeble-minded, one brother epileptic, three brothers and one sister died in convulsions in early life. The patient had convulsions in early life and at intervals as he grew to manhood. In January, 1907, he had a convulsion and during the following few days made attempts at suicide with laudanum and by stabbing himself with a knife. Five months later he repeated the suicidal attempts. One day he left his home to purchase a newspaper and two hours later met a woman who had been his mistress. They were seen talking together in normal tones for several minutes, when he drew a revolver and shot her twice, causing her death. He then walked a few

steps and shot himself above the right eye and fell to the street. He recovered from the wound and was tried for murder. At the trial it was shown that since early life patient had been subject to periods of severe headache, when he would cry, jump and roll about the floor, was unable to sleep and at times would leave his fish barrow, sometimes with the money from his sales, and walk the street, returning after a time and continuing his work with no explanation of his conduct. While in prison awaiting trial he was often violent and destructive, at times refusing food, and emphatically denied that he had shot anyone. When he was admitted to an institution for the insane, December 3, 1907, he denied that he had been arrested or in prison or that he had shot anyone. He said the injury to his eye was caused by a man striking him. He had vivid aural and visual hallucinations. For several weeks he remained dull, taking little interest in his environment or the visits of his wife and mother. After he had been with us about four months he became more active, a good ward worker and cheerful. He told us the first thing he remembers after coming to the hospital was the carol singers passing through the ward on Christmas Day (22 days after his admission). He apparently had an almost complete amnesia from Thanksgiving Day, 1906, until Christmas Day, 1909, though in that interval he had followed his trade as a fish peddler with some regularity, had shot a woman and himself, had been confined in prison and passed through a criminal court and detained for some time in an asylum for the insane. The only things he recalled that occurred during that time was that he had chains on his legs, which was during his prison confinement, and the face of one of his fellow patients was familiar to him, though he could not give his name or where he had seen him. (They had been cell mates in prison.) While with us he had several convulsions of the grand mal type and periods of irritability and headache.

This case is of considerable medicolegal interest, and there are three things to be considered in weighing the evidence: 1. Was the man malingering or feigning insanity? 2. Was the amnesia a true amnesia and one due to epilepsy? 3. Finally, was the amnesia due to the self-inflicted pistol wound and covering a period of several months prior to the wound?

Hallucinations of all the senses are prominent in epileptics. They have visions of paradise and walk in gardens of flowers, listening to beautiful music. They smell and taste poisonous things in their food. Voices control their actions by telling them what to do, and this alone may sometimes make them very dangerous.

We have known one young epileptic who shot and killed his brother, and the only motive that could be learned at the trial was that a voice had continually told him for some time preceding the crime to "Do it now! Kill him now! You must kill him!" The same man previously had made a number of attacks on his fellow workmen without warning, these being probably prompted by the same voice.

In summing up let me say that the cause of epilepsy is as yet unknown, but that heredity and excesses play a great part in its cause cannot be denied. The mental states vary within wide limits. They may be melancholy or maniacal, at times they are suicidal and are frequently homicidal, they are usually irritable, and almost always hopeful of recovery.

## THE MANAGEMENT OF THE PUERPERIUM AND ITS MINOR ABNORMALITIES.*

By B. A. FEDDE, M.D.,

BROOKLYN, N. Y.

It is doubtful if in all the realm of medicine and nursing there is a class of patients which has suffered so much neglect and abuse as that of the lying-in woman and her newborn.

When a woman has proved her incapacity for continuous sustained work in any other direction, or has apparently outlived her usefulness in every other capacity, she can yet do confinement nursing among the poor for a wage of eight to twelve dollars a week. She has been present at a few confinements where a harassed practitioner of a previous generation officiated, and his methods, opinions, and results are for her the *ne plus ultra* of obstetrics. Time goes on, and art and science advance; but if the man convertible to new ideas after forty is a rarity, what shall be said of the woman? Ignorant, weak, or lazy, hidebound by antiquated medical opinions and midwives' and old grannies' wisdom, she presents a veritable Chinese inertia to any attempt at bringing modern science into the lying-in chamber. She will tell your patient that it is dangerous to comb the hair during the first week, that fresh air is dangerous for fear of "catching cold," that there is no use in putting the child to the breast until milk secretion is well established, meanwhile dosing it with sweet oil to move the bowels, and sugar water—each spoonful tasted by herself—to still its thirst and hunger, and whiskey or gin or paregoric for wakefulness at night. The infant's breasts will be rubbed with sweet oil until it is lucky indeed to escape without abscess. If there is catarrh, a squirt of milk from the breasts is more efficacious than cleanliness alone; and if for any reason the baby does not take the breast the remedy is for her, the nurse, to spit upon the nipple or have the mother do so. She will frighten the patient with the terrible danger to life in lying otherwise than flat upon the back, and will cause many an hour of mental anguish by wise diagnosis of tongue-tie and retention of urine.

If you catch her at any of her absurdities, or if the patient inadvertently gives you a hint of them, she is mortally offended, and your patient is made to feel through the whole of her stay that she, the nurse, is being imposed upon. She will shirk all she dares of the irksome cleanliness you demand with regard to eyes, mouth, nipples, and diapers, and may not dare to change the mother's clothing for a week, but does not hesitate to give vaginal douches unless you expressly forbid them.

There is little or no use in trying to teach any of these old crones, for they are Oriental in their obstinacy and the setness of their ways; and though they give a diplomatic assent to your opinions and orders, you must not delude yourself with the belief that you are implicitly obeyed. They "never had any trouble," and have always done as they do now. In short, Sairey Gamp still typifies a good many confinement nurses.

The first step in the management of the puerperium is the selection of the nurse. This is not easy. The wives of day laborers and carpenters and small clerks cannot afford graduate nurses, and there seem to be few young women available at a weekly wage of ten to fifteen dollars, which seems to be all

*Read before the Norwegian Hospital Alumni Association January 8, 1913.

that this class of patients can afford to pay. It is best to have the patient send her nurse to you for an interview, that you may impress your ideas upon her. I have found it necessary to print the following set of rules for the nurse, and to hold her strictly to them:

To the Nurse—You must observe these rules strictly.

*The Mother.*

She is to be bathed every day.

The genitals must be washed twice daily with lysol solution. *No douche.*

In addition, pour boiled and cooled water over the genitals whenever she has urinated or the bowels have moved.

Fresh absorbent cotton must be frequently applied. Do not touch that part of the cotton which comes in contact with the genitals.

Wash your hands with soap and water each time before tending the parts.

The mother must not lie on the back more than a third part of the time.

Make sure that the mother urinates at least three times a day.

The nipples are to be washed with alcohol before each time the child is put to the breast. Let the alcohol evaporate. Wash the nipples after nursing with boric acid solution or plain water.

The mother may have ordinary diet including fruit, except where otherwise ordered. She must not have coffee after 12 o'clock noon; tea, pork, onions, cabbage, turnips, cake, or anything else indigestible.

*The Child.*

The diaper must be changed as soon as it is wet or soiled. *Three times a day is not enough.*

Mouth and eyes must be gently washed with boric acid solution four times a day.

The navel string must not be disturbed.

Use only castile soap in washing baby.

The child shall nurse for 15-20 minutes every two hours by day, every four hours by night. *Not more frequently.*

In addition it must have in the course of the day at least six tablespoonfuls boiled, cooled water without sugar.

Nothing else must be given without my orders.

Feel frequently if the feet are warm.

Perfect cleanliness in every respect is required.

I revisit the patient on labor day, then once a day for the next five days; again seven, nine, and twelve days after labor. At the last visit a pelvic examination is made, unless a repaired perineum makes advisable deferring it for some weeks. Under normal circumstances the patient is permitted to sit up in bed several times on the fifth day, and to get out of bed for an hour on the tenth day. Red lochia have by this time almost ceased. If not, a capsule containing strychnine sulphate, gr. 1/60; quinine sulphate, gr. iss; extract of ergot, gr. ij, is given four times a day until the lochia are white.

But many cases will show deviations from normal. Breasts, nipples, digestive system, bladder, and uterus are all working under novel or unusual conditions, and are apt to suffer. Some patients with a large appetite may continue to eat at the same rate as formerly, giving rise to acute indigestion or autointoxication in the form of rheumatoid pains in muscles and joints. The bowels should be evacuated within 36 to 54 hours after delivery, by castor oil. This, although nauseous, is the most satisfactory cathartic, giving a uniformly liquid stool. A few drops of essence of peppermint in the spoon and over the oil, or a little whiskey will render it less unpalatable, particularly if it is followed by black coffee or orange juice. Almost all other cathartics administered after two days of constipation give a stool of which the first part is solid, lumpy, often hard, and the succeeding discharge soft and watery. The lumps will give a great deal of distress to a patient with perineal tear or hemorrhoids. The cathartic by mouth may require a supplementary soapsuds enema to start the movement.

*Bladder.*—This must be emptied three or four times a day. Where the patient cannot urinate upon the bedpan at first, hot perineal stupes may be applied for twenty minutes. This failing, unless there are plain contraindications, the patient may be propped up to a sitting posture and given a glassful of cold water to drink. It may be necessary for the nurse to leave the room, that the patient may have her wonted privacy for urinating. If none of these measures succeeds, before resorting to catheterization I give morphine sulphate 1/16 gr. dry on the tongue. One-half hour afterward the patient again attempts to urinate. Failing, the dose is repeated once or twice, each time allowing one-half hour for the morphine to diminish inhibition. In my series of over three hundred cases it has been necessary to catheterize only three times—once before I began to use morphine, and twice in successive confinements of another patient since. The latter found out for herself that the presence of the nurse in the room caused inhibition.

*Breasts.*—Many women feel more comfortable with a supporting binder for the breasts. I seldom use it, however, not caring to trust the judgment of the untrained nurse in the matter of pressure. Where the breasts are pendulous and tend to congestion in the dependent portions a binder is loosely applied with folded towels in the axillæ for support. If the child has died a tight breast binder is usually applied. Some men do not touch the breasts in this case, but give enough morphine to keep the pain in abeyance until the congestion subsides—usually two to five days.

The nipples have been bathed with alcohol and rubbed, pulled, and twisted with cold cream daily for the last few months of pregnancy. As indicated above, they are washed with alcohol a few minutes before each nursing, and the alcohol allowed to evaporate. If fissure appeared, I formerly applied with a tuft of cotton before each nursing the following: Orthoformi, ʒss; tr. benzoini co. q.s. ad. ʒss; but it has not always been satisfactory, and I get better results lately by treating at once all fissures with silver nitrate, 10 per cent. solution, repeating once daily in weaker strength, say 2 per cent. Care must be taken to paint only the fissure. While the nipples are very sore, some form of shield may be necessary, or the breast must be pumped periodically. I prefer a wide, shallow, saucer-shaped all-rubber shield which when applied encloses practically no air. The nurse must be told to boil it frequently, and it should be discarded as soon as practicable.

*Uterus.*—Daily note is made of the position and height of the fundus, its consistency and sensitiveness, as well as the condition of the iliac fossæ. The lochia are inquired about, but the progress of perineal repair is not inspected, as I believe nothing can possibly influence non-union excepting perhaps bacterial vaccines. Some men make it a practice to

give a couple of prophylactic doses of mixed vaccine (Van Cott's) where there has been much injury done to cervix or perineum. If the lochia become offensive, a vaginal douche is given—always by myself—of the following: Boiled water, 2 quarts; tr. of iodine, ½-ounce; and the importance of Fowler's position is emphasized to nurse and patient.

The *temperature* and *pulse* of the lying-in woman are very easily influenced by slight causes. Fretfulness of the baby, visitors, sore nipples, congested breasts, overeating, an uncongenial nurse, or a family spat may give a rise in no way differing from the initial records of serious disease. I append a chart showing my experience, giving the most reasonable cause in each case:

Post-Partum Rises in Temperature.

| Number of Case | Day of Puerperium | Initial Temperature. Degrees | Duration of Pyrexia Days | Clinical Diagnosis |
|---|---|---|---|---|
| 1 | 2 | 101 4 | 2 | Constipation |
| 5 | 5 | 100. | 1 | Sore nipple |
| 9 | 9 | 100.8 | 14 | Pneumonia |
| 12 | 1 | 101 | 1 | Fibrin absorption |
| | 4 | 102 | 1 | Constipation |
| 15 | 8 | 100.4 | 9 | Femoral phlebitis† |
| 19 | 7 | 100.4 | 1 | Constipation and engorged breasts |
| 22 | 4 | 100.4 | 2 | Constipation and breasts |
| 24 | 2 | 104.2 | 14 | Puerperal sepsis |
| 28 | 7 | 102.8 | 3 | Mental disturbance. Poor drainage |
| 32 | Labor | 101 | 1 | Fibrin absorption |
| 41 | 4 | 100.2 | 1 | Breasts, inflamed hemorrhoids |
| 46 | 3 | 100.6 | 4 | Breasts |
| 49 | 7 | 102.4 | 1 | Constipation |
| 71 | 9 | 101.2 | 1 | Constipation |
| 75 | 5 | 102.6 | 1 | Erysipelas of breast |
| 84 | 2 | 102.6 | 1 | Indigestion |
| 86 | 3 | 100.4 | 1 | Retained secundines |
| 89 | 9 | 99.2 | 2 | Erysipelas of breast |
| 92 | 3 | 101.6 | 1 | Constipation |
| 95 | 3 | 101.2 | 3 | Poor drainage |
| 104 | Antepartum and 1st | 102.8 | 3 | Preexisting pyelitis |
| 112 | 5 | 105.4 | 7 | Unknown general infection. Not genital |
| 115 | 3 | 100 | 1 | Breasts |
| 132 | 4 | 102.6 | 1 | Poor drainage |
| 141 | 4 | 100 | 1 | Excitement. Sore nipples |
| 148 | 7 | 100 | 4 | Grippe |
| 150 | 3 | 100.6 | 2 | Muscular rheumatism. Autointoxication |
| 165 | 7 | 100 | 1 | Breasts |
| 179 | 1 | 103.4 | 2 | Constipation |
| 192 | 4 | 101.4 | 1 | Breasts |
| 194 | 8 | 101 | 2 | Mastitis |
| 211 | 4 | 104 | 4 wks. | Puerperal sepsis |
| 215 | 4 | 100.4 | 3 | Poor drainage |
| 216 | 12 | 104 | 2 | Erysipelas of breast |
| 229 | 1 | 100.6 | Throughout puerperium | Preexisting tuberculosis |
| 236 | 9 | 100.2 | 1 | Mental excitement |
| 243 | 3 | 101 | 1 | Constipation |
| 251 | 4 | 100.2 | 2 | Breasts |
| 256 | 2 | 100.2 | 4 | Breasts. Poor drainage |
| 272 | Labor | 100.4 | 1 | Fibrin absorption |
| 279 | 2 | 101.2 | 3 | Preexisting pyelitis |
| 303 | 4 | 100.8 | 1 | Drainage |

†Died.

I believe the commonest cause of disturbance is constipation, relative or absolute. Some patients have a hold-over appetite which they do not curb, and with the intestinal sluggishness which comes with a relaxed abdominal wall and lying in bed, they get attacks of autointoxication even though the bowels are said to move.

Defective drainage probably comes next. Possibly it should rank first. It will be remembered that in the supine position the axis of the vagina extends upward and forward, causing a pool of lochial discharge to accumulate in the upper part of the vagina, bathing the bruised and torn cervix, and discharging only the overflow. To my mind it is a great wonder that not two cases in three "go septic" under the circumstances. My personal impression from a very limited number of cases is that the better the nurse the more apt is the patient to have toxic absorption, probably because the good nurse does for her patient many things which the poorer kind of patient must sit up to do for herself. Since case No. 256, where the point was forcibly impressed upon my mind in consultation, I have made it a rule to keep the patient in Fowler's position as much as possible, raising her up on pillows beneath the shoulders, or a washboard inserted between springs and mattress, and blocked up. Edgar has tried to improve drainage by ordering a diurnal revolution in bed, the patient lying successively upon back, side, belly, other side, and back. Few of the less intelligent women can see the sense of this; besides, lying on the side alone will not materially improve drainage, since the axis of the pelvis is apt to be tilted upward in the lateral posture.

Engorgement of the breasts seems at times the only assignable cause for febrile movement. It may be controlled by moderation in the use of fluids, saline cathartics, firm bandaging, the breast-pump, and massage. I never permit an untrained nurse to massage or "rub" the breasts. There is too great danger of mastitis or abscess from infection of the lacteal ducts.

Other causes of pathological puerperium can be determined by patient investigation. It must be borne in mind that serious complications may arise without alarming temperature. Thus in case No. 15, phlebitis had appeared two days before the temperature reached 100°.

Finally, there is one point of very great importance in the management of deviations from the normal puerperium—early consultation. When you watch a disturbance grow from its earliest beginnings you may very easily mistake it for something either less or more serious than is really the case; and a consultant coming in with a fresh, unprejudiced mind, free from anxiety, will be of enormous advantage to you. There is something paralyzing in the gradually settling conviction that your case is "going septic," and that you *may* have been the one at fault; your ideas of treatment become fogged, and you need help to clarify them and give definite direction to your efforts.

On the other hand, it is very easy and tempting to gloss over and minimize disturbances which are apparently not septic. I have in mind a patient who called me four days after labor, after discharging in despair the man who had confined her. Her history was as follows: She had her eighth child after a short normal labor on a Sunday afternoon. Two hours later she began to suffer from severe griping pain about the umbilicus. The abdomen began to swell; at present it has the size of a full term pregnancy. Vomited all ingesta from the first. The bowels moved yesterday after calomel and citrated magnesia ordered by the physician. Since yesterday she has had frequent scanty stools, with much griping and tenesmus. No blood in the stools. Patient has been annoyed all day by a metallic tinkling sound in the lower abdomen. Temperature, 99°; pulse, 102, fairly good in quality. Heart and lungs normal. Abdomen immensely distended and tympanitic. No peristalsis heard on auscultation. Liver dulness diminished. At two-minute intervals a metallic tinkling is distinctly audible at the bedside. Uterus—Fundus not found. Cervix firm, slightly tender. Bilateral laceration. Rectum empty. Lavage accomplished nothing in relieving distention. Stomach empty. Diagnosis Intestinal obstruction, probably from volvulus.

She was at once removed to hospital. Repeated enemas failed to affect the distention, and a laparotomy was done the next day. Peritonitis, enormous general intestinal distention, and a ruptured duodenum were found. The patient died shortly after leaving the table. The seat of obstruction was not found at operation. No autopsy.

In this case no credit can be claimed for the diagnosis, nor do I feel that the physician was severely blamable. I fear the same errors of interpretation might be made had the case been mine from the beginning. Let us analyze the

Symptoms with Their Obvious Explanations.

| | |
|---|---|
| Abdominal pain | Afterpains |
| Constipation | Normal for 2 or 3 days |
| Vomiting | Indigestion. Sunday dinner |
| Diarrhea and tenesmus | Calomel and magnesia |
| Distention | Indigestion |
| Reports of patient's distress | Officiousness of nurse, who had no confidence in attendant |

The physician informed me later that temperature and pulse had at no time during his observation exceeded normal limits.

To recapitulate, the points I wish to emphasize are:

1. Fowler position in every case from the first.
2. Early consultation when complications, all but the very simplest, occur.

378 Ninth Street.

## EARLY DIAGNOSIS OF TUBERCULOSIS WITH NOTES ON INTERNAL ANTISEPSIS.

By C. AM ENDE, M.D.,

NEW YORK.

The following observations were suggested by a case which supports my previously reported results in tuberculosis. The most salient points in the patient's illness are as follows:

Mrs. S., aged 66 years, after a protracted prodromal period, during which in 1903 no tubercle bacilli were found in her sputum, had in May, 1905, her first pulmonary hemorrhage. Three more followed at lengthy intervals. The last one, on Christmas day in 1910, left her so low that her children induced her to give up her position as janitress in the tenement house in which she lived. Partly owing probably to the effects of previous medication, taken in pill form, consisting of one grain of quinine with one-fifth of a grain of iodoform, and creosote, which was taken on and off, which medication was now continued steadily, she recovered to the extent that in August, 1912, her expectoration became reduced in the morning to the hawking up some glairy mucus. Four successive examinations by the Board of Health showed this mucus free from the tubercle bacilli. There was no reaction to tuberculin.

The idea that recognition of her actual trouble, tuberculosis, during especially the earlier parts of her protracted prodromal period, when her sputum was free from bacilli, might have saved her very much trouble, led to the following experiments. These were conducted with the Moro salve in preference to tuberculin injections. This salve, which contains equal parts of tuberculin and lanolin, when rubbed in at the pit of the stomach produces within two days characteristic efflorescence.

Designating this case of Mrs. S. as Case I of our series, one may state that the absence of a reaction to the Moro salve, supported by the bacteriological findings and physical symptoms, indicated the absence of any active tuberculous process.

Case II.—A very fine granular eruption, disappearing in a few days, was the type of reaction in a man, aged 45. He had been treated off and on for some time for a laryngitis involving the cords and for pulmonary catarrhal conditions. Two months ago he had a light pulmonary hemorrhage.

Case III.—A much more distinct miliary reaction appeared in Mr. S., aged 22. He called October, 1910, for increasing emaciation and debility. He had a short, hacking cough without expectoration, and except a slight distant voice on the left side there were no other positive tuberculous symptoms. He was given the pills, but the emaciation yielded but little, and only after about one year could he begin to work again. When it appeared safe because of a supposedly sufficient immunization, and perhaps of dislodgement of bacilli, the d'Arsonval current was used for production of pumonary hyperemia with a most agreeable effect on the patient.

Case IV.—A slight but distinct reaction was also given by K., aged 15, who shortly before had been declared healthy in a physical examination.

Case V.—A very distinct, almost pustular reaction was given by a young lady who came for treatment because of increasing emaciation and debility. There was bad family history. She reported an improvement after taking the first lot of pills.

Case VI.—Another distinct reaction was observed in a young lady, also with a bad family history. She came because of a short, dry, hacking cough. Immediately she was treated with the pills. Considerable euphoria was reported and also the disappearance of the cough. She has not returned.

Case VII.—P. S., aged 7, was seen because of arrest of growth and increasing apathy. He gave a slight but distinct reaction. He had a bilateral cervical adenitis, the chain of enlarged glands extending on the left side to, and on the right below, the clavicle. He received pills having half the strength of those prescribed for the adult, creosote in 1-grain pills. The *x*-rays were also used. The glands disappeared with the exception of one on the right side, which felt like a soft compressed pea. Under continued treatment there occurred a considerable increase in growth, strength, etc.

Case VIII.—E. M., aged 7, was brought November 6, 1912, because of a short, dry, hacking cough, lasting for as much as two hours at bedtime. She was apathetic and there were dark rings under the eyes, which disappeared soon under treatment. In contrast to the injections the rubbing in of the salve amused her greatly and produced an intense, nearly pustular reaction. She was immediately given the pills, two-thirds the strength of the adult dose. Two weeks later the father reported what he thought was a remarkable improvement. A repeated inunction in January, 1913, was followed by a much finer reaction. There was a decided improvement in the patient's physique.

Case IX.—A faded macular dermatitis appeared in Mrs. K., who was treated three years ago out West, but not as long as directed. She believes she has been healthy since then. She has no cough, etc., but is again taking the pills, although reluctantly.

Case X.—Her 8-year-old daughter gave no reaction.

Case XI.—Mrs. M. R., reported in my previous paper, gave two rather pale little macula. She continues treatment. There is no cough. This permanent absence of cough in all kinds of weather seemed singular, although already observed in the case of A. D., reported in the previous paper. He positively denies having coughed during the long time since his recovery.

Case XII.—No reaction was obtained from Mr. R., who feared tuberculosis because of a severe bronchitis, his poor build, and a bad family history. His fears could thus be allayed.

Reviewing these cases it should first be said that their number is far too small for the establishment of any definite principle, but as they all indicate an improvement, in some cases even permanent cure, in high percentage, five out of six, now their brief analysis seems in order.

In its earliest stage the disease was probably detected in Case VIII. The rapidly disappearing, fine granular reaction of Case II denotes also a very early detected infection, but one that already had gained a foothold, as evidenced by the rupture of a probably small blood vessel under a strain ordinarily sustained without injury. The pronounced euphoria soon following combined tuberculin absorption and drug administration has suggested a repetition of this course of treatment. Cases V and VI indicate the influence of wise friends and the necessity of the physician keeping these patients strictly under control. Cases III and VII, already for some time under treatment, although their physical symptoms are as yet uncertain, demonstrate the value of the Moro reaction in the absence of bacilli carrying sputum. The rather rapid and apparently complete cure of Mrs. S. so soon after her nearly fatal hemorrhage at Christmas, 1910, may depend upon the development of considerable immunizing substance from the earlier medication. The faded or very light reactions of Cases IX and XI suggest an as yet incomplete cure, while in the apparently completely cured patient Case I as well as in two healthy subjects, Cases X and XII, no reaction appeared.

Thus the Moro reaction enabled one to detect in this small series of cases the presence of tuberculosis in its earliest incipient stages as well as in its obscure and latest stages; it demonstrated the absence of the disease; and to a degree the intensity of the reaction seemed proportionte to the intensity of the disease. Children did not resist. Except in a case of early developing hip joint disease the reaction has revealed the enemy at a time when his destruction is not so very difficult.

An arrested normal development, emaciation, a general laxity, and a short dry hacking cough were the principal, though rather obscure, symptoms that suggested the use of the salve. Some but not all these patients could be made to comprehend that a person may have "consumption" entirely unknown to themselves or friends, and that at this earlier stage the disease is more easily curable than when further advanced in its destructive course. If these observations are corroborated, considerable control over tuberculosis may develop.

It may be noted that the active agent in the production of the Moro reaction is tuberculin, which, according to the most plausible theory, is a substance elaborated by body cells upon stimulation by a toxic material occurring in the bodies of dead tubercle bacilli, which substance is inimical to, and destructive of these bacilli when living. The basic element then in this process is the dead bacilli; without them immunizing tuberculin does not develop. With our chemicals the process must differ. In the usually slowly advancing disease effective bacilli are absent. Therefore their presence can only have been brought about by the chemicals which kills them. After that the two processes may well go on, so to speak, hand in hand, immunization predominating over the killing, and vice versa. If correct this may explain the reported unusual results. In this connection the much disputed and neglected internal antisepsis should appear as capable of utilization in proper occasions. Its condemnation probably has resulted from its use in insufficient dosage.

It may be stated that Binz[2 3 4] demonstrated as early as 1867 a general antiseptic effect for quinine and later the specific effect upon the plasmodium malariæ. The established rational basis for internal antisepsis may permit an answer to the statement by F. J. Watkins:[5] "As yet no remedies are known that directly limit the growth or destroy the bacteria of puerperal infection." With the exception of one case, in which the infection met with had been carried directly into the abdominal cavity, all the other cases yielded to the following treatment. In a case of this condition with temperature 104° 5-grain quinine pills were given every four hours until temperature fell to about 102°. In addition there was given local treatment. With the pills there were ordered one dram of iodoform, one dram of quinine, one ounce of glycerin, and one yard of 10 per cent. iodoform gauze, which was cut into strips ½ inch wide and tapering toward one end. Two such strips were tied together to make one of double length. Then according to the temperature 20 or 30 grains of iodoform were rubbed up with some glycerin, to which was added about 10 to 15 grains of quinine, and this mixture was rubbed into the gauze strip. After proper toilet of the parts as much as convenient of this gauze strip was packed into the offending uterus, and the rest was packed around the cervix, forming a tampon supporting the uterus. The patient soon began to experience comfort. With a very high temperature the packing should be repeated the next day. Irrigations may follow. In one bad case several full packings were necessary and these were followed by some erosion of the outer mucous membrane of the uterus.

Doses of quinine that may appear dangerously excessive were employed in a sufficient number of severe infectious diseases to establish that when that drug is given with sweet spirits of niter in large doses, no other undesirable results followed than some passing auditory disturbances. In one desperate case, declared hopeless by two consultants, about two and a quarter ounces of quinine were given to a little girl aged 9 years in the course of six weeks with the best result. This warranted the employment of this drug in full doses in typhoid fever.[6] When used as below it reduced the duration of the disease to twenty-four days in my most protracted case and to ten days in the case of shortest duration. The dangerous cold baths that are productive of pneumonic complications were not needed; the delirium was light; in the twenty-four days case the consumption of food, which was liberal on the sixth, rose on the eighth day to two quarts of milk, two eggs and a roll; a week later oysters, soups, and the like could be added. The patient left his bed on the eighth day and stayed up

a little longer each day; thus he was quite strong when he went out on the twenty-fourth day. This should justify the medication, which consisted of administering, seven times a day at first, a capsule containing 5 grains each of muriate of quinine and subnitrate of bismuth, with one drop of creosote; with any less at the beginning the temperature would rise, index like. After four to six or seven days less could be given. The dose of the sweet spirits of niter was from ½ to 1 dram daily. The rapid improvement of the patient, the simplification of treatment, and the shortening of the disease would seem to justify this treatment in suitable cases. If not used alone it may well supplement vaccines, which are satisfactory only as a prophylactic. Of course large single doses of quinine were often given in typhoid[7] fever, but apparently not every day, as this method seems necessary to destroy the myriads of Eberth bacilli. Quite likely an antitoxin develops during the treatment, as in tuberculosis, both the antitoxin and the quinine working in unison.

The pitiable conditions ultimately occurring in tuberculous ostitis may warrant recalling that in the previously reported case of N. H.[1] a rather rapid recovery ensued upon the use of the *x*-rays, which supplemented the internal immunizing processes. The presence of these seems essential because in their absence the *x*-rays increase the discharge as in two cases of purulent otitis media. As long as such patients are able to walk one or more trials of this method are easy and at any rate not harmful.

## Medicolegal Notes.

**Malpractice—Acts Constituting.**—In an action for malpractice in the treatment of a girl of seven, the plaintiff alleged that the girl was suffering from an injury to the sciatic nerve due to a fall from a porch. The defendant was called in three days after this occurrence and at first diagnosed the case as appendicitis and afterwards as typhoid fever, for which he treated her for about 21 days. The patient had been playing about as usual during the two days after her fall. Medical experts for the plaintiff answered a number of hypothetical questions tending to sustain the contention that the child was suffering from an injury to the sciatic nerve, caused by the fall. But these physicians also testified that the history of the case during the two days after the fall would exclude any injury to the sciatic nerve. There was therefore no evidence in the case to substantiate the plaintiff's theory of an injury to the sciatic nerve caused by the fall. The defendant, on the other hand, now contended that the child had been from the beginning afflicted with infantile paralysis. The plaintiff's medical witnesses testified that the child's symptoms might have been diagnosed by men of ordinary skill in the medical profession as typhoid fever, multiple neuritis, or infantile paralysis, and that the treatment given by the defendant in no way contributed to the subsequent condition of the child. It was held that there was, therefore, no evidence in the case that the treatment by the defendant was negligent or unskillful. The most that could be said was that he did not discover the infantile paralysis. From the evidence he could not have cured it if he had. It could not therefore be said that his failure to discover its presence, or his subsequent treatment, was responsible for the child's subsequent condition.—Brydges v. Cunningham, Washington Supreme Court, 124 Pac. 131.

**Accidental Death—Wound Causing Disease.**—In an action upon an accident policy where the assured died of erysipelas, the question was whether the death was caused solely by actual, violent and accidental means. The plaintiff, his widow, contended that the assured received a slight accidental injury to his left cheek, causing an abrasion of the skin, and that this injury resulted in "traumatic erysipelas." The attending physician of the assured testified to the discovery of the abrasion of the skin. He also testified to his opinion that the disease from which the assured died was wholly infectious, and could not have resulted, except through infection of some wound or abrasion of the skin. He also testified that it made its first appearance at the edges of the alleged wound, and that in his opinion it resulted solely from the infection of such wound. His evidence was corroborated by other medical testimony and was held to be sufficient to sustain a finding that the death of the assured was the proximate result of the wound or abrasion. No direct evidence was introduced to show any of the circumstances which caused the abrasion. It was apparently very slight, and how or when it was inflicted did not appear. Its appearance was held to support the finding of the jury that the cause of the wound was violent and external.

In the absence of direct evidence, the presumption arose that the wound was not intentionally inflicted either by the assured or by another. That presumption was almost equivalent to a presumption that it was inflicted through accidental means, although the authorities stop short of announcing the presumption in the latter form. They do hold, however, that an inference may be drawn from the presumption first stated by the triers of fact that the wound was caused by accidental means as the only other alternative.—Caldwell v. Iowa State Traveling Men's Assn., Iowa Supreme Court, 136 N. W. 678.

**Medical Examiner as Insurance Company's Agent.**—In an action upon a mutual benefit certificate it appeared that the insured had stated in his application that he was a farmer, when he was in fact a saloonkeeper. It was contended, however, that the physician who took the medical examination was the insurance company's agent and knew the falsity of the statement, and on that account the company was estopped from forfeiting the policy by reason of the false statement. It was held, however, that while a medical examiner is regarded as the agent of the company issuing the certificate of insurance for which he makes the medical examination, and that the company will be chargeable with knowledge of information possessed by him contrary to disclosures made in such medical examination by the applicant, the medical examiner is not the agent of the insurer for anything more than is contained in the medical examination and his certificate thereto, and the insurer cannot be charged with any knowledge of information had by him outside of that agency. In this case the statement was made in the application and not in the medical examination. The application was signed by the applicant and acted upon by the local judge before the examination was made. The examining physician, as such, had no duty to perform relative to the application, and did not in any manner represent the company in making or accepting the application.—Sovereign Camp Woodmen v. Hall, Arkansas Supreme Court, 148 S. W. 326.

**Instructions to Jury—Malpractice.**—In an action for malpractice, which resulted in a verdict for the defendants, it was held on appeal that an instruction which simply called the attention of the jury to the inquiry whether, under the evidence, the defendants were negligent in failing to anticipate and provide against the occurrence was held not to be harmful to the plaintiff, where the court also told the jury that it did not intend to indicate to them any opinion as to the facts in the case or that it had any opinion as to what facts were proven or disproven.—Steele v. Stanhurst, Indiana Appellate Court, 98 N. E. 733.

**Examination of Expert by Court.**—In an action for personal injuries a medical expert was asked by the court what he meant by a relaxed sacro-iliac joint and whether the witness would be surprised if certain other surgeons had said that such cases were extremely rare and that they had only known two or three cases of movement of the sacro-iliac joint. It was held the questions were not improper, in view of the judge's caution to the jury not to consider the matter.—Beebe v. Greene, Rhode Island Supreme Court, 82 Atl. 780.

## THE PATH FOR PROGRESS IN MEDICAL EDUCATION

EFFORTS in recent years to raise the standard of medical education have proved very illuminating to all who are striving to better education no matter in what particular field, so P. P. Claxton, U. S. Commissioner of Education, states in the introduction to Bulletin No. 4 of the U. S. Bureau of Education, a monograph by Dr. George E. MacLean on "Present Standards of Higher Education in the United States," just issued. Dr. MacLean, in reviewing the history of the progress of standards in education, convinces one of their necessity. It is to be hoped that this publication will aid in a quicker appreciation of right standards on the part of all. But while public opinion is not educated enough to discern what is needed, and while educators lack insight into what constitutes medical education, it will remain the duty of the profession itself to determine a general practical standard. A physician who has made mistakes—who has diagnosed pleurisy as appendicitis, or who has failed to recognize ectopic pregnancy—truly knows wherein our present system of medical education is weak. A great diversity of opinions might be expressed as to just in which direction the path for progress lay. Two things, however, are apparent as obstacles to progress, the non-recognition of two types of medical schools and the effect of the present examinations for license on medical education.

The movement for standardizing medical education in this country needs careful guidance. In this movement it has been lost sight of that there are two phases of medical education, that which is university in character and that which is technical. University teaching aims to give a broad vision of problems from a philosophical standpoint, while technical teaching aims only to give practical training. In our country our few universities excel in giving good practical training while the smaller schools, which should have no other excuse for existing, fail, for the most part, to train their students in practical work. The university professors, desirous of raising the plane of their teaching above that of practical instruction, have realized the necessity of the students coming to them better prepared in the sciences and languages because the advanced instruction, that they wish to give, bewilders the ill-prepared student. This, then, is where the movement for raising the standard of entrance requirements to our medical schools began. The lesser schools, instead of recognizing their proper aim, have, in some instances, tried to give university teaching when they were even unable to give adequate practical instruction. These schools are a necessity and would play an important and valuable part in our system of medical education if they would realize their limitations and aim to graduate skilled practitioners, men well trained in physical diagnosis, laboratory technique, and bedside experience. The university, on the other hand, should give all this and more. They have a much higher calling. Their teaching should be of such a character and such far-reaching influence as to attract special students, and to develop an investigating turn of mind which would lead them into research and finally prepare them for teaching. It must be understood that unusual work is not for every man and it is the especial duty of universities to develop the exceptional student. To do this their whole teaching must be on a high educational plane else they will fail to fulfil their mission. Of late there has been some talk of adding a fifth year to the medical curriculum. In the case of the universities which require their matriculates to be well grounded in the sciences, this is unnecessary, while in the lesser schools it would be wiser to make the present four years of some value in practical training and experience. It would be greater progress to bring about four strong rather than five weak years.

In this matter of a standard for medical education, the State sooner or later is called upon to make some ruling in connection with the granting of licenses. In doing so it has usually been guided by medical school authorities instead of heeding what is best for the student and the public. The State is rightly concerned only with practical knowledge. It should seek to protect the public by refusing to license as practitioners of medicine, men who have not had the requisite training and experience. It should determine whether the candidate for license has the skill to diagnose a case of incipient pulmonary tuberculosis, not whether he knows the latest immunity theory. If the State were to abandon its previous policy of holding only written examinations on text-book subjects and were to conduct a practical examination like that of the Conjoint Board of the Royal College of Physicians of London and the Royal College of Surgeons of England, it would immediately cause all medical schools to give practical medical training. It would also stimulate the students to seek practical experience wherever they might find it. At present it is to their interest only to cram the contents of a quiz-compend. By introducing a sound method of giving thorough practical examinations the interests of the public would be better safeguarded. No one thinks of entrusting lives to locomotive engineers simply on bookish requirements. Practical experience is the criterion. In medicine it should be the same. The present method of examining has served its purpose in bringing the medical schools up to a certain standard, but now it only hampers further progress by its untoward effect on practical instruction.

## PELLAGRA IN THE UNITED STATES.

It is only within recent years that pellagra has been heard of in this country. When reported first in Alabama, the disease was practically unknown to most of the medical profession of the United States. Now it occurs frequently in the practice of a large number of practitioners. It appears to have spread with great rapidity and has been reported from at least forty States and the District of Columbia. In the Annual Report of the Surgeon General of the Public Health Service of the United States for the fiscal year 1912, it is stated that complete and accurate statistics for the entire United States are lacking, but from an extensive inquiry begun by the service some months ago, and soon to be completed, it is conservatively estimated that since 1907 there have occurred not less than 30,000 with an average case mortality of about 38 per cent. computed on exact figures for eight States studied. In many sections of the country, the disease now prevails in epidemic form and is menacing the life and health of the entire population. The report goes on to say that "When consideration is given to the nature of the disease, its chronicity and termination often in invalidism, insanity, or death, the lack of definite knowledge as to its causation and transmission, the unsatisfactory results of treatment, its rapid and continuous spread, the class of people affected and the uneasy state of the public mind in many places, then the thorough investigation of this mysterious disease assumes immediate importance." In another part of the report, it is pointed out that whether the disease is increasing or not, cannot be told in the absence of a record of the occurrence of cases. The disease, at any rate, is being recognized more frequently than in former years, owing to the greater familiarity of physicians with the symptoms. It is suggested that the disease should be made notifiable in all States, so that its relative prevalence may be known, as information as to its relative frequency of occurrence in different localities and under varying conditions will undoubtedly aid materially in determining the cause of the disease.

So far as the Public Health Service is concerned, work is being pushed as rapidly and adequately as funds will allow in the direction of ascertaining the causation of pellagra, and other necessary facts in connection with the disease. A fairly complete laboratory is now in working order, and investigations have been made along the following lines: Clinical and laboratory studies on pellagrins received in the wards of the marine hospital at Savannah, Ga., which has been made the chief base for the study of pellagra by the Service; the collection of statistics on the geographical distribution and prevalence of pellagra in the United States; and epidemiological studies of the disease in the field. Passed Asst. Surg. C. H. Lavinder and Asst. Surg. R. M. Grimm are in charge of the work at Savannah. However, the work is as yet only in its infancy in this country, and more money by far is needed ere the problem can be grappled with as effectively as the gravity of the situation demands. The progress of the work is hampered by lack of money and as pointed out in the report, while studies have been carried on as actively as possible, the want of sufficient money and the necessary facilities have prevented investigation on a scale commensurate with the problems involved. These problems cannot be adequately met by the bacteriologist or clinician or pathologist alone. To hope for satisfactory results, complete and extensive studies must be made from all sides, and in order to do so larger appropriations will be required.

The point must be emphasized that in certain parts of this country pellagra is a distinct menace to health, that it is increasing, and that the only way possible to check its spread is by thoroughly investigating the disease from all angles. So long as its causation, distribution, and other essential details are unknown, it is impossible to devise steps for its prevention. Parsimony in a matter which directly relates to the health of a goodly proportion of the population would be extremely unwise policy.

---

## TUBERCULIN.

During the past few years tuberculin has come again into favor, and it is generally allowed that this substance is useful as a therapeutic agent. So far as is yet known tuberculin is hardly deserving of the praise lavished upon it by some of its enthusiastic advocates, nor is it so valueless as some of its opponents assert. Perhaps its therapeutic value lies between these two extreme views and to designate it as useful is to say the proper thing. However, while the majority are practically agreed as to its use, there is no agreement whatever with respect to the form in which tuberculin is best employed nor as to the most satisfactory system of dosage. Alexander Fleming, writing on the subject in the *Practitioner*, March, 1913, points out that the discrepancy between the views of various authorities regarding the form and dosage of tuberculin is wide. Tuberculins are made from the human and the bovine types of bacillus. The most recent communications as to the relative frequency of these two types of tuberculosis in man appear to point to the fact that almost all the infections in adults have been caused by the human type. Park, indeed (*Journal of Medical Research*, December, 1911), concluded that bovine tuberculosis is practically a negligible quantity in adults. In children it caused a marked percentage of cases of abdominal tubercle and cervical adenitis.

Fleming draws attention to the fact that in all other forms of infection one aims at using as a vaccine an organism as nearly as possible identical with the infecting organism. Consequently, in employing tuberculin for adults we ought to use tuberculin made from the human type of tubercle, except in the few cases where the bovine type is found. Of the forms of the human tuberculin employed there are still two main groups, old tuberculins and new tuberculins. Old tuberculins are made from the filtrates of tubercle broth-cultures, and the new are prepared from the bodies of the bacilli of such cultures. Wright and his followers use exclusively the bacillary emulsion, an emulsion of the ground-up bacilli. The doses of this are always small.

Latham using the same preparation, begins with similar doses, but before pronouncing a patient cured very largely increases the dose. Speaking in a discussion of the Royal Society of Medicine, March, 1912, he divided his cases into two groups, chronic nonfebrile and febrile. In the febrile cases he commenced with a small dose and increased it very gradually, repeating the dose every two or three days. Emery considered the old tuberculin the most potent for good or evil. Wilkinson has urged the use of a sequence of different tuberculins. The doses of these he rapidly increases, so that the reaction which he obtains becomes progressively less and tolerance to tuberculin is obtained. Thus it will be gathered that although tuberculin is useful there is too much divergence of opinion with regard to the best form to be used and the dosage to render it a wholly reliable or satisfactory remedy.

## CZERNY ON THE ORIGIN AND TREATMENT OF CANCER.

Czerny of Heidelberg, who has for many years devoted his life to cancer research, delivered a semipopular lecture on this subject before a scientific body (Urania Society) of Berlin on March 5, a report of which appears in the *Münchener medizinische Wochenschrift* of April 1. The distinguished lecturer had at the same time completed his fortieth year of cancer research. The subject first considered was the percentage of operative or knife cures. This amounts in the skin and superficial localities to 80 or 90, in the female breast the corresponding figure is 40, the observation period occupying five years. In cancer of the gastroenteric tract the percentage of cures amounts to from 20 to 30. The proportion of lifesaving for cancer in general when treated with the knife is about 40 per cent.

Experiments upon hundreds of thousands of animals of many species, chiefly in the form of inoculations, not only between members of the same species but between unlike species (mice and rabbits) were discussed. It was recalled that the first one to study mouse cancer in its spontaneous transference—Morau—was of the opinion that the affection was communicated by bedbugs. A step in advance was marked by Rous's discovery that the inoculable virus passes through a bacteria-tight filter. It is also probable, the speaker said, from the studies of Fischer and others, that various microorganisms are able to secrete a toxin which can set up cancer.

Czerny then took up *x*-ray cancer. We now have notes of 65 cases of this genesis and the author believes that *x*-ray dermatitis acts simply as a port of entry for a cancer generating organism. Knowledge of the precancerous state is highly important because opportunity is afforded to extirpate these disease foci (gastric ulcer, mastitis, moles, etc.). It is of course possible from analogy that an ultra microscopic organism may transmit the disease through sensible parasites, whether these be stinging insects or tics or intestinal parasites injected with uncooked food. Whatever may be the causal agent, relative virulence must be a marked factor.

Nonoperative resources must find a wide field in inoperable cases and in the prevention of relapses. Statistics show that bad cases may be improved and that a considerable proportion of doubtful cases may actually be cured by intensive and prolonged therapy. In conclusion Czerny hopes for much good in the future through the establishment of cancer retreats, which shall be similar in nature and object to leproseries and tuberculosis sanatoria. It is rather discouraging to learn that a man of Czerny's ability, after forty years of study of this subject, can discuss the present status of the problem only in such vague and general terms, without revealing a single new fact or even the suggestion of one.

### Occupation for Convalescents.

A very great advance in the management of the insane in recent years has been the providing of useful occupation for them, whereby their minds are diverted and a useful channel is found for their motor restlessness. But the blessing of work is not for the insane alone, and a movement has been started for the teaching of handicraft to chronic invalids and convalescents whereby the ennui inseparable from enforced idleness is markedly relieved. In the initial number of the *Clifton Medical Bulletin* (April, 1913) Miss Mary Irving Husted, Director of the Industrial Department at the Clifton Sanatorium, writes entertainingly of what has been done in that direction at Clifton Springs and elsewhere. There are two classes of patients especially to whom the opportunity for light work is a boon. Surgical patients who are so far convalescent that they no longer need the constant attendance of a nurse have many weary hours whose tedium is greatly relieved by the following of a handicraft such as basket weaving, which gives an outlet for the imagination in varying the patterns and puts no strain on the eyes. Chronic invalids also, whose confinement to bed for weeks at a time is most wearisome, find relief and entertainment in the same or a like occupation. Those able to leave the bed are taught leather carving or rug weaving. These handicrafts not only give occupation for the hands but also direct the thoughts and keep the mind from dwelling unprofitably or injuriously on the physical condition. The department at Clifton Springs was opened in December of last year, and already, Miss Husted says, the good effects upon the physical and mental condition of the patients have been most gratifying.

## News of the Week.

**Examination for Public Health Service.**—The United States Treasury Department announces that Boards of commissioned medical officers will be convened on May 5, and again on June 9, 1913, for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health Service. Candidates must be between 23 and 32 years of age, graduates of a reputable medical college, and of good moral standing. After four years of service, assistant surgeons are entitled to examination for promotion. Assistant surgeons receive $2,000; passed assistant surgeons, $2,400; surgeons, $3,000; senior surgeons, $3,500; and assistant surgeon generals, $4,000 a year. Further information or invitation to appear before the board of examiners may be obtained from "The

Surgeon General, Public Health Service, Washington, D. C."

**For Women Physicians.**—Governor Sulzer of New York on April 18, signed the Tudor bill recently passed by the Legislature, providing that where women are required to undergo physical examinations in order to obtain employment, the examinations shall be made by women physicians.

**City Death Rate.**—During the week ending April 12, there occurred in New York City 1,460 deaths, giving a death rate of 14.18 per thousand, as compared with a total of 1,600 deaths and a death rate of 16.14 for the corresponding week of last year.

**Island Site Rejected.**—At a meeting of the Board of Estimate of New York City last week, the proposal to build on North Brother Island a hospital for contagious diseases to receive cases from the Borough of the Bronx was rejected by the Board. The island site was favored by certain of the residents of the Bronx who have objected to the placing of the hospital nearer home, and who have heretofore blocked its erection on any of the sites so far considered in the borough. Owing to the lack of such a hospital, the death rate from contagious diseases among children is now higher in the Bronx than elsewhere in the city.

**Smallpox on Steamship.**—The *Pannonia,* which arrived in New York last week from Mediterranean ports, reported one steerage passenger ill with smallpox. The patient was removed to Swinburne Island, and the other passengers, who had occupied the same compartment, were taken to Hoffman Island for observation.

**Saturday and Sunday Association.**—At a recent meeting in New York of the Hospital Saturday and Sunday Association the treasurer reported collections during the current year of $117,707, an increase of $11,719 over last year, and by far the largest amount collected in the thirty-three years of the association. The number of associated hospitals is now forty-seven.

**Oppose Hospital Site.**—The New York Merchants' Association has asked Governor Sulzer to withhold approval of the plans for the Mohansic State Hospital for the Insane and for the New York State Training School for Boys, both of which it was proposed to erect at Yorktown Heights in Westchester County. This action has been requested pending the enactment of a bill prohibiting the establishment of such institutions within the Croton and Catskill watersheds from which the water supply of New York City is derived.

**Dr. Friedmann in New York.**—After a prolonged stay in Providence, R. I., where he was permitted to treat private patients, Dr. Friedmann returned to New York on April 18 in response to the request of the Public Health Service officials, taking him to task for the neglect of the experiments undertaken in this city. During his visit to Washington last week, Dr. Friedmann treated fifty patients at the George Washington University Medical School. An attempt was made to receive permission for him to practise in the District of Columbia without the formality of a license, but it was blocked in the Senate by Senators Gallinger, Penrose, and others, some of whom were far from complimentary in their remarks.

**Fire in Laboratory.**—Ether fumes escaping from a still in the chemical laboratory on the third floor of the Cornell University Medical College, New York, on April 19, ignited and started a fire. Fortunately, the flames were extinguished before much damage was done.

**Trouble at Bellevue.**—The internes became the patients at Bellevue Hospital one day last week when chicken salad served in the doctors' dining-room at luncheon temporarily incapacitated almost the entire staff. All of the victims recovered, but the integrity of the chicken in the salad was doubted.

**Camden, S. C., Hospital.**—Work has been begun on the new Camden Hospital in Camden, S. C., which is the gift to his native town of Mr. Bernard Baruch of New York. The hospital will cost about $35,000 and will contain twenty beds. Its support will be derived from a fund of $75,000 left by the late Mr. John Burdell of the town for the purpose of treating the sick poor of Kershaw County.

**New York State Board of Medical Examiners.**—Dr. Lewis Stephen Pilcher, 145 Gates Avenue, Brooklyn, has been appointed examiner in diagnosis on the State Board of Medical Examiners in place of Dr. Glentworth R. Butler, who has resigned on account of temporary illness. Dr. Pilcher was graduated from the University of Michigan in 1862 with the degree of A.B., later with the degree A.M., and in 1866 with the degree M.D. Dr. Pilcher served for a time in the Medical Corps of the U. S. Navy and then settled in Brooklyn. He has served either as surgeon or consulting surgeon on the attending staffs of most of the hospitals in Brooklyn. For many years he has been the Editor of the *Annals of Surgery.*

Dr. Herbert U. Williams, Dean and Professor of Pathology of the Buffalo Medical School, has been appointed examiner in bacteriology on the State Board of Medical Examiners in place of the late Dr. Hiss. Dr. Williams was graduated from the University of Pennsylvania in 1891. He is President of the American Association of Pathologists and Bacteriologists. He is pathologist to the Buffalo General Hospital and the County and Sisters' Hospitals.

**Personals.**—Sir William Osler, who arrived in New York on April 14, and left at once for Baltimore to attend the opening of the Henry Phipps Psychiatric Clinic of the Johns Hopkins Hospital, was accompanied by Dr. W. McDougall of Oxford and Dr. F. W. Mott of London. The party will spend six weeks visiting the large cities of the East before returning to England.

Dr. Simon Baruch of New York was the guest of honor at a reception on March 31, in Camden, S. C., where he at one time resided.

**Hall of Health.**—The spring cleaning campaign in New York City received fresh support at a meeting held at the Museum of Natural History on April 16, when the new Hall of Health, under the direction of Prof. C. E. A. Winslow, was formally opened. Over a thousand persons attended the meeting and listened with enthusiasm to Commissioner Lederle's plans for improving the health of the city.

**Gifts to Charities.**—By the will of the late Moses Weinman of New York bequests of $5,000 each are made to Mount Sinai Hospital, Beth Israel Hospital, the Presbyterian Hospital, St. Vincent's Hospital, and the Montefiore Home for Chronic Invalids.

The Presbyterian Hospital, New York, receives $1,000, and the Roosevelt Hospital $1,500, by the will of the late Miss Margaret E. Mitchell.

Bequests of $500 to Beth Israel Hospital and $300 to Lebanon Hospital were made in the will of the late Wolf Cohen of New York.

The Brooklyn Homeopathic Hospital receives $3,000 by the will of the late James C. Atwater of Brooklyn.

The House of Rest for Consumptives, New York, is the only charitable institution receiving a direct bequest by the will of the late J. Pierpont Morgan. For this institution, a fund of $100,000 is created to be used for corporate purposes and to be known as the "Amelia Sturges Morgan Memorial Fund." The will, however, also contains a clause requesting the residuary legatee, Mr. Morgan's son, to continue as long as it may seem necessary, the same assistance given by Mr. Morgan during his lifetime to the Society of the Lying-In Hospital, New York. This is said to have amounted to $100,000 a year.

**Medical Society Elections.**—Tennessee State Medical Association.—At the annual meeting, held in Nashville on April 10, the following officers were elected: *President,* Dr. William D. Haggard, Nashville; *Vice-Presidents,* Dr. E. M. Holmes, Murfreesboro; Dr. Robert Mann, Memphis, and Dr. Hiller P. Larimore, Chattanooga; *Secretary,* Dr. Perry Bromberg, Nashville.

Hampden District (Mass.) Medical Society.—The following officers were elected at the annual meeting in Springfield on April 15: *President,* Dr. George D. Weston, Springfield; *Vice-President,* Dr. Abbott L. Cooley, Chicopee Falls; *Secretary-Treasurer,* Dr. Hervey L. Smith, Springfield.

Tolland County (Conn.) Medical Society.—The 121st annual meeting of this society was held at Rockville on April 15, when the following officers were elected: *President,* Dr. Wright B. Bean, Rockville; *Vice-President,* Dr. Cyrus B. Newton, Stafford Springs; *Secretary-Treasurer,* Dr. E. P. Flint, Rockville.

Twelfth District (Ind.) Medical Society.—The following officers were elected at the annual meeting held at Fort Wayne on April 9: *President,* Dr. James W. McKinney, Bluffton; *Vice-Presidents,* Dr. Thomas J. Creel, Angola, and Dr. W. E. Smith, Decatur; *Secretary-Treasurer,* Dr. L. T. Rawles, Fort Wayne.

Rock Island County (Ill.) Medical Society.—At the annual meeting at Rock Island on April 8, the following officers were elected: *President,* Dr. W. D. Snively, Rock Island; *Vice-Presidents,* Dr. John W. Seids, Moline, and Dr. Henry J. Love, East Moline; *Secretary,* Dr. W. D. Chapman, East Moline; *Treasurer,* Dr. A. T. Leipold, Moline.

Springfield (Mass.) Academy of Medicine.—The annual meeting was held on April 8, when officers were elected as follows: *President,* Dr. Walter R. Weiser; *Vice-Presidents,* Dr. E. A. Bates and Dr. A. O. Squier; *Secretary,* Dr. John M. Birnie; *Treasurer,* Dr. George L. Schadt.

New London County (Conn.) Medical Society.—At the annual meeting held in Norwich, officers were elected as follows: *President,* Dr. William H. Gray, Mystic; *Vice-President,* Dr. Anthony Peck, Norwich; *Secretary,* Dr. E. O. Winship, New London.

**The Late Dr. Prince A. Morrow.**—At a recent meeting of the Society of Sanitary and Moral Prophylaxis, the following minute was adopted: "The death of our honored President, Dr. Prince A. Morrow, has come to the members of this Society as a deep personal sorrow, and is an irreparable loss to the cause which he so ably and so heroically led. Almost single-handed he inaugurated in 1905 a movement in this country which is already nation-wide, and which promises to be the first successful attempt, by means of public enlightenment, to reach the root of an evil of the ages and a curse of mankind. A man of great intellectual force, of strong personality, and of unflinching courage, he entered upon the task against unusual odds, inspired others with his own enthusiasm, and founded this, the first Society of its kind in America, which has already become the parent of over thirty similar Societies in as many different states. In the guidance of this movement which had to deal not only with a delicate subject, but also with a false public sentiment, the greatest wisdom was required. Dr. Morrow led the way with unerring judgment and tact. To-day there are arrayed in the ranks of his followers many of the foremost and conservative men and women of the country. To those who came more intimately in contact with him as his personal associates on committees, his death comes as a personal bereavement; to all of us it is a loss which will be deeply felt for a long time to come. All knew him as a man of great ability, of the highest character, courageous, and true; and as a Society, we place upon our records this brief testimony of our love and high esteem. We extend to his family our deep sympathy in their great bereavement and irreparable loss. *Signed:* Edward L. Keyes, Jr., M.D., Thomas M. Balliet, M.D., Henry P. de Forest, M.D."

It was also resolved to hold a memorial meeting of the Society on May 22, at the Academy of Medicine.

**The Late Dr. Bristow.**—The following Resolutions were passed by the Council and adopted by the New York Academy of Medicine; *Whereas,* The Council of The New York Academy of Medicine has learned with profound sorrow of the death of Dr. Algernon Thomas Bristow, therefore be it *Resolved,* that the Council hereby records its appreciation of Dr. Bristow, the man and the physician. He became a Fellow in 1901, and served as Vice-President from 1906 to 1909. As an officer, as a member, and in his private practice he exemplified all that is best in the medical profession. He combined to an unusual degree the practical and the ideal in his work. Dr. Bristow was a man of great public spirit and much interested in all the activities of the Academy. His wise judgment and genial personality will be greatly missed. Therefore be it *Resolved,* that a copy of these resolutions be sent to the family and to the medical journals. Signed: William M. Polk, M.D., President; Charles F. Adams, M.D., Recording Secretary; Wisner R. Townsend, M.D., L. Emmett Holt, M.D., Committee of the Council.

**Obituary Notes.**—Dr. Edward Sawyer Bacon of Providence, R. I., a graduate of the Harvard Medical School, Boston, in 1889, consulting aural surgeon to the Butler and Providence City Hospitals, and surgeon to the Rhode Island Hospital, and a member of the American Medical Association, the Rhode Island State and Providence District Medical Societies, the New England Otological and Laryngological Society, and the Rhode Island Ophthalmological and Otological Society, died at his home after a long illness, on April 8, aged 50 years.

Dr. Frederick Clift of Kaysville, Utah, a graduate of the University of Cambridge, England, in

1870, and of the Keokuk Medical College, Keokuk, Ia., in 1891, editor of the *Utah Medical Journal*, and a member of the Utah State and Davis County Medical Societies, being secretary of the latter, died at his home, from pneumonia, on March 28, aged 66 years.

Dr. John H. Winch of Northfield, Vt., a graduate of the University of Vermont College of Medicine, Burlington, in 1880, a former member of the Vermont State Legislature, moderator of the town of Northfield, and a member of the Vermont State and Washington County Medical Societies, died at the Heaton Hospital, Montpelier, on March 28, aged 57 years.

Dr. George Martin of Montreal, Quebec, a graduate of Laval University Medical Department, Montreal, died at his home, from diphtheria, after a short illness, on April 1, aged 31 years.

Dr. John Jay Craig died at Columbia, Pa., on April 11 at the age of 33 years. He was graduated from Jefferson Medical College in the class of 1901, subsequently becoming resident physician in the Philadelphia Polyclinic Hospital and later serving in the same capacity at Dr. Trudeau's sanitarium at Saranac. He was a member of the Lancaster County Medical Society, of the Medical Society of the State of Pennsylvania and of the American Medical Association.

Dr. Egbert D. Doolittle died at Easton, Pa., on April 12 at the age of 67 years. He was graduated from the Bellevue Hospital Medical College in the class of 1870 and he was at one time President of the Lehigh Valley Homeopathic Medical Society.

Dr. James Strong Cameron of Red Bluff, Cal., a graduate of the University of California, Medical Department, San Francisco, in 1868, and a member of the California State and Tehama County Medical Societies, died at his home on March 24, aged 67 years.

Dr. Clara J. Alexander of Boston, a graduate of the Woman's Medical College of Pennsylvania, Philadelphia, in 1889, and formerly a member of the staff of the New England Hospital for Women and Children, died recently in Mysore, South India, where she had gone to study Eastern diseases.

Dr. Robert Lindsey Carter of Gloucester, Mass, a graduate of the Hahnemann Medical College and Hopital, Chicago, in 1894, died at his home suddenly on April 10, aged 41 years

Dr. William T. Shelton of Umatilla, Fla., a graduate of the Louisville Medical College, Louisville, Ky., in 1872, died at his home on March 30, aged 76 years.

Dr. Franklin A. Shurtleff of Somerset, Mass., a graduate of the Albany Medical College, Albany, N. Y., in 1864, and a member of the school committee of Somerset for over forty years, died at his home on April 9, aged 75 years.

Dr. Parley H. Johnson of Adams, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1865, and a member of the New York State and Jefferson County Medical Societies, died suddenly in Watertown, from heart disease, on April 16, aged 73 years.

Dr. Henry G. Addy of St. John, N. B., a graduate of the University of Vermont College of Medicine, Burlington, in 1862, a medical officer in the United States Army during the Civil War, a commissioner of the General Public Hospital, St. John, and formerly on the Council of Physicians and Surgeons of New Brunswick, died at his home recently, aged 78 years.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

ADMINISTRATION OF THE INSURANCE ACT—LONDON MEDICAL BENEFIT COMMITTEE—VENTROFIXATION OF THE UTERUS—A HOSPITAL DEADLOCK—VERONAL—OBITUARY.

London, April 4, 1913

The working of the Insurance Act continues to give rise to excited discussions, some of them almost justifying the gibe that the law seems to have imbibed much of the provocative character of its author. At the London Committee for its administration yesterday a proposal was made to ask the Medical Benefit Sub-Committee to report as to whether the present system can be improved and if so to submit recommendations. The proposers said they all knew how the patients were being "fobbed off at the end of the day" at a surgery far away from their homes and so on. Prior to January he said they had not less than 1,500 doctors in contract practice in London and to-day far fewer. The chairman interposed—1,258—on which a rather unseemly contention arose, the speaker saying the chairman had misled those as to the number who would be on the panel and the chairman indignantly denying the charge. The exact number is not much to the point at issue and the effervescence subsided. The speaker added that the clubs and doctors had both cooled down and if there were 1,300 on the panels he believed 3,000 might become available for the insured under proper arrangements. He suggested a conference between doctors on and off the panels and the sub-committee might lead to good results. Dr. Turner seconded, as he thought the time had come to consider how, within the four corners of the act, they could modify the service so as to succeed in working it whole-heartedly. He had fought the act from the first because, while approving thrift and insurance, conditions were such that men of his profession ought not to be asked to submit to them. He had obtained replies to a specific question to medical men, whether the insured were getting as good attendance as under the old contract practice. The answers showed they were not, many being from those in favor of the act. He had, too, a despatch-box full of complaints.

Dr. H. H. Mills supported the motion but from a different point of view. Highly respected men informed him that they thought things satisfactory. The act emphasized the needs of the East End of London for the first time he declared. But surely every one who knew the East End would contradict him on this point for the need had been published freely for many years. A full discussion followed and the resolution was eventually carried by a large majority. So now one must await the report of the Medical Benefit Sub-Committee which it is to be hoped will be founded on extensive and impartial enquiry.

The gynecologists assembled in full force at the Royal Society of Medicine for the debate which had been arranged for them on "Ventrifixation of the Uterus," a proceeding which has been adopted in so many cases as to give rise to a good deal of comment, not a little of it adverse. The general practitioners who watch the cases before and after operation seem less enamoured of it than the specialists so that the discussion was well worth attending.

It was opened by no less than three carefully prepared papers on different points. The first was by Dr. W. S. A. Griffith, who laid down the indications which he considered called for suspension in consequence of failure of the supports to maintain the position necessary for the comfort of the patient and to enable her to perform laborious duties. The cases are twofold. (1) When the uterus is at or nearly at the normal level but retroversion or retroflexion of the body and broad ligaments causes prolapse of the ovaries. (2) When prolapse of uterus, ligaments, and ovaries is considerable and associated with varying degrees of vaginal, vesical, and rectal protrusion. In both these groups many cases are sufficiently relieved by pessaries, though some women prefer operations to their prolonged use with the associated douchings, etc. He did not support the practice of those who operate on patients in poor general health which they attribute to the retroversion but which is a symptom rather than a cause of ill health.

The second paper was on the technique and by Professor Briggs of the Liverpool University. He advocated a purely peritoneal direct ventrofixation over a limited appropriately chosen area, *i.e.* a site immediately adjacent to the pelvic floor. This operation he defended as the outcome of his personal experience of 600 cases.

The third paper, on "After Results," was by Dr. A. E. Giles. He confined his remarks to the specific operation which he terms hysteropexy and of which he has previously published results down to July, 1909. He has since done 199 cases, making his total 508. The general health was reported to be improved in over 90 per cent., the position of the uterus to remain good in over 95 per cent. Pregnancy following hysteropexy did not disturb the position and there were no complications in labor.

Dr. Herbert Spencer was the first speaker after the three papers were read. He at once expressed surprise at the frequency with which the operations were performed in these cases. He had himself only done it 27 times in 1,000 abdominal sections, for he considered it unscientific and by no means free from danger. He was influenced further by the many cases which he had seen of failure of the operation to relieve the symptoms. He saw that in Dr. Giles's valuable investigation into the after-results 42.2 per cent. had pain afterward though it was less than previously in 32.5 per cent. In his opinion both ventrosuspension and -fixation, as usually performed were dangerous, unscientific operations, which often give rise to peritoneal bands, and these on many occasions had caused strangulation of intestine. For procidentia after the menopause he admitted fixation might be a useful adjunct to colporrhaphy and perineorrhaphy, care being taken to perfectly close the peritoneum over the bladder.

Dr. A. Donald confined his remarks to cases of mobile retroversion for which many operations were done in the hope of removing symptoms attributed to congestion induced by the displacement. But he held that we have no reliable evidence that congestion is so induced nor that it could give rise to such changes in the endometrium as would cause menorrhagia, metrorrhagia, and leucorrhea. Stitching up the uterus in these symptoms was therefore unscientific. Endometritis was often the cause—never the result of retroversion. His practice was to curette these cases and pay no regard to the position of the uterus.

Dr. Macnaughton-Jones said he had never performed hysteropexy and did not think fixation should be done during the child-bearing period.

Miss Ivens said her experience was confined to Gilliam's operation—in some cases with Mays' modification. One case complicated by chronic appendicitis had been fatal; 93 per cent. followed up were satisfactory. Dr. Handfield Jones had seen much distress from the fixation having been done at too high a level and had given immediate relief by setting the uterus free again. The patient should be prepared by ten days' treatment in bed with hot douches and glycerin tampons. Dr. Arnold Lea said pessaries were seldom of any use except in simple retroflexion following confinement. He had done the operation 75 times, mostly for backward displacement. Dr. Hubert Roberts said retroversion needed no operation or if in any case it did it should be directed to improve the pelvic floor. Dr. H. B. Whitehouse did not approve the increasing tendency to fix the uterus which often failed to relieve. Cases should be carefully selected. He had seen one of intestinal obstruction brought about by a band resulting from fixation. Dr. Fairbairn thought those who did hundreds of fixations must be living in the mid-Victorian period when displacements were regarded as of supreme importance. Dr. Farquhar Murray reported observations made with Mr. Glendining on the capacity of the bladder before and after ventrofixation—half the cases showing increase and half decrease after operation. Dr. Walter Tate had done 44 ventrifixations in St. Thomas's Hospital between 1900 and 1910. He only advised it, when pessaries and other methods failed, for women in the prime of life who had to earn their living. He had found it of some use in distressing cases of incontinence of urine from weakness of the sphincter. Fixing the uterus seemed to support the neck of the bladder.

The president, Dr. A. Routh, said ventrofixation was often a useful addition to laparotomy for removal of appendicitis, but he hardly thought it necessary in other cases. His primary cases did not exceed 3 per cent. of his abdominal sections and comprised cases in which prolapse of one or both ovaries complicated retroversion. In such ventrofixation had its chief use. Curettage, plastic operations, etc., often gave more relief than fixation. If all minor proceedings failed then ventrofixation might be performed.

A curious deadlock has arisen over Marlow Cottage Hospital. The position of the building is unsuitable and for two years a scheme for a new hospital has been arranged to cost £2,000, for which over £1,300 has been subscribed and the charity commissioners have sanctioned a loan. Mr. Langley has offered to give a site and grant the loan on easy terms. At a public meeting yesterday in support of the scheme and pledging to assist the committee in raising the funds after some discussion a division resulted in a tie, 43 votes for and 43 against. The chairman, who is Vicar of Marlow and a trustee of the hospital, declined to give a casting vote.

Death from veronal is getting a common heading in the newspapers. At an inquest on a widow of 36 the other day an open verdict was returned, the only evidence being that she had taken different medicines for insomnia without advice. Probably she read about this in the papers.

Yesterday an inquest was held concerning Capt. Stacey, late I.M.S., who was found dead in his bedroom with a partly smoked cigarette in his fingers and veronal tabloids strewed on the floor. It

was known he had been in the habit of taking them for sleeplessness. In a letter to a brother he had said: "I shall be going away to-night," but had never threatened suicide and the brother did not understand the phrase about going away. Death from veronal was proved by medical evidence. Verdict, suicide under temporary mental derangement.

Surgeon-Lieutenant-Colonel A. Brebner has died at the age of 72. He graduated at Aberdeen, M.B. and C.M. in 1862, took also L.R.C.G. Edinburgh and next year joined the Army Medical Service. He served in the Bhootan expedition of 1865, was at the recapture of Dewangiri and received the medal with clasp. He proceeded to the M.D. degree at his university in 1873 and retired in 1888.

Dr. G. Templeton, of whose death you will have heard as the tourist in Norway who was lost in the snow, practised in London for some years. A telegram yesterday announced that his body had been found by a private expedition, eight miles from Finse. He had been lost exactly a week, during which various expeditions had searched for him without success. He was fond of traveling, a clever linguist and accomplished musician, 42 years of age, and graduated at Edinburgh.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

YAWS MISTAKEN FOR LEPROSY—SEGREGATION OF LEPERS—OPENING OF THE CEBU HOSPITAL—NEW HOSPITAL AT ZAMBOANGA—TAX ON POLISHED RICE—PERSONAL.

MANILA, P. I., February 28, 1913.

THE Bureau of Health has undertaken a second collection of lepers in the Moro Province, and this time, has reached considerable territory that has heretofore not been covered. At the Port of Davao, sixty-nine persons that were suspected of having leprosy were assembled who had been collected from various places in the province that bears the same name. On careful examination, practically all of them were found to be cases of yaws in the third stage. This again demonstrates in a forceful manner the unreliability of the average lay reports with regard to leprosy. The Bureau of Health has been receiving information for many years that large numbers of lepers were presumably at large in Davao Province. Yaws does however result, when untreated, in horrible deformities and extensive ulcerations, and unless careful microscopical examinations are made, it is not an infrequent error even for medical men to mistae them for lepers. Persons being presented who had other diseases accords with the experience which the Bureau of Health has had in the early collections of lepers which were made in 1906, it being not an infrequent occurrence to find one hundred or more persons collected as lepers, who on careful examination, were found to be sufferers from syphilis, yaws, paralytic deformities, elephantiasis, madura foot, and other diseases.

So far as known, with this collection of lepers, with the exception of a few who have escaped, all lepers throughout the Philippine Islands have now been segregated and transferred to the leper island of Culion or are undergoing special treatment at the San Lazaro Hospital at Manila.

The Legislature, which has just closed, has finally provided funds for opening and maintaining the Southern Island Hospital at Cebu. It will perhaps be remembered that this seventy-bed institution was completed last year. This hospital is second only to the Philippine General Hospital of Manila, and is modern in every respect and prepared to handle medical, surgical, obstetrical, and tubercular cases in wards or private rooms. Owing to Cebu being tributary to a large amount of territory in the Southern Islands, the hospital will no doubt relieve a large amount of distress and suffering and prevent many deaths from surgical and other diseases that can be saved with hospital facilities.

Under the auspices of the Episcopal Church, with the aid of the citizens of Zamboanga, the construction of a thirty-bed hospital is about to be begun at that place. An institution of this kind will also be capable of doing a large amount of good, because at the present time in the entire Moro Province, with the exception of the military hospitals, there is no place where civilians can receive adequate medical relief.

The bill which the Bureau of Health introduced into the Legislature, which had for its object the reduction in the use of unpolished or decorticated rice, failed of passage, but there are good prospects that at the next session it may become a law. Under the provisions of the bill it was proposed to bring about the desired object by placing a tax of two cents a kilo upon polished rice and no tax upon the unpolished rice. The legal determination as to whether a rice was polished or unpolished was to rest upon the amount of phosphorus pentoxide which it contained. All of that which upon analysis was found to contain 4 per cent. or more of phosphorus pentoxide was to be regarded as unpolished rice, and that which contained less was to be regarded as polished rice. In other words, the amount of the beriberi preventing principle was to be determined in terms of phosphorus pentoxide. This test would have been capable of easy application by the mere appearance of the rice or by staining it with methylene blue. The polished rice stains very deeply while the unpolished rice only takes a small amount of stain.

The Bureau of Health is now preparing to inaugurate a very extensive campaign of education, both by the distribution of printed literature and by public lectures as to the origin, manner of spread and prevention of beriberi.

Dr. Herbert Coe, of the Washington State Board of Health, is at present making an extended tour of the Philippines for the purpose of acquainting himself with the health work conducted in the Islands.

7. A Convenient Anatomical Device. R. M. Green.

**1. Conduct of Labor without Vaginal Examinations.**—C. M. Green concludes that the common custom of making frequent vaginal examinations during labor is a bad one and deserves to be classed as "meddlesome." These examinations disturb and often hurt the patient, they add to the risks of infection, they give no informa-

tion that cannot generally be obtained by external examination, except as to the condition of the cervix, and the possibility of prolapse of the cord or a fetal extremity. Except in hospitals, to which naturally many abnormal cases are sent, the greater majority of cases are normal as far as the fetal passenger and the maternal passage are concerned, and when delay occurs it is much more generally due to defective pains. Frequent vaginal examinations do not remedy this difficulty, and the obstetrician's efforts can be more profitably employed than in making them. The author considers the conditions which would warrant or necessitate vaginal examinations during labor. Pathological conditions usually call for operative procedure, from low forceps to abdominal section. Most of these procedures necessitate vaginal invasion; but every vaginal examination shadows the prognosis, if Cesarean section is finally decided on. Antepartum hemorrhage, pregnancy toxemias with convulsions, compound or other abnormal presentations, minor relative disproportion between pelvis and fetal head, complicating neoplasms, prolapse of the funis, and evidence of impending fetal asphyxia, surely necessitate treatment involving invasion of the vagina But in the absence of these more or less grave complications, the only indications for vaginal examination in cases which at the beginning of parturition bid fair to be normal seem to the author to be only the prolongation of labor beyond reasonably normal limits of time, that is, ineffectiveness of the maternal powers, and suspected prolapse of the cord or a fetal extremity.

2. **Diabetes in Infancy and Childhood.**—J. L. Morse notes that diabetes occurs in childhood more frequently than is generally supposed. The frequency of diabetes increases directly with age. A possible explanation for the lesser incidence of diabetes in childhood may be the somewhat greater sugar capacity at this age than in adult life. The symptoms in children are, of course, in the main the same as in the adult—polyuria, polydypsia, emaciation and constipation. Polyphagia is, perhaps, more common. Symptoms of gastric disturbance are said to be more common in the child (Stern). Disturbances of the skin, eye and nervous system are less frequent. Marked changes in the disposition are, however, very common, the child often becoming quiet, morose and sad. Enuresis is often the first symptom to call attention to the trouble, while in others the first thing noticed is the presence of flecks of sugar on the clothing, vessel or floor. Another early and suspicious symptom is irritation of the external genitals.

5. **Progress in Diagnosis and Treatment of Intussusception.**—W. E. Ladd states that the time has passed when a recovery from intussusception following laparotomy and reduction is to be considered a surgical curiosity. In the last five years there have been successfully treated at the Children's Hospital in Boston ten times as many cases of intussusception as in a period of five years previous to 1908. The medical practitioner deserves part of the credit for this gratifying improvement for having brought the cases earlier to the hospital. In the future if he will bring still earlier and doubtful cases one can hope to determine the diagnosis with the aid of the *x*-rays in time to cause another marked reduction in mortality. Patients with intussusception operated on within thirty-six hours from the onset of symptoms may be expected to recover.

1. **Poliomyelitis and Variola.**—F. Proescher describes the microorganisms which he has detected in smears made from emulsified brain and spinal cord of monkeys that had been affected with the experimental form of poliomyelitis. These microorganisms included the following: Extremely small cocci stained pale blue, deep blue, or metachromatic violet. These were on the limit of visibility (0.1 micron), appearing single or in chains or groups. Deep blue diplococci shaped like gonococci, approximately 0.2 micron in diameter; short, thick, oval bacilli, about 0.1 micron long, in form of diplobacilli, and single ones, one to two microns long, stained deep blue; slender bacilli, about two microns long, stained pale blue; a spirochete form, from three to five microns long, slightly curved, and stained pale blue. The bacilli are the predominating form. The virus is extracellular, intracellular, and intranuclear Smears from sterile pustular contents of cases of small pox stained with methylene azure carbonate showed many microorganisms, their size ranging less than 0.2 micron to one micron. There were isolated or diplobacilli; chains or groups of short oval bacilli; very small diplococciform pneumococci and bean shaped diplococci, all divided by a small, pale stained zone; large, round cocci, sometimes divided into four parts like tetragenus. The majority of these microorganisms were intracellular and quite often intranuclear. Some of the epithelial cells were entirely filled with these microorganisms. Extracellular, they were few in number. These were also found in different strains of glycerinated vaccine and in the filtrate of greatly diluted vaccine filtered through Berkefeld filter V.

2. **Pathology of Neuralgia.**—C. McConnell believes that at the present time the question of the pathology of neuralgia resolves itself into the histological changes that are found in the nerves and which one understands as indicating neuritis. The difficulty that arises may be somewhat obviated if the term neuritis is not restricted to those changes alone that are purely inflammatory. It is next to impossible for such alterations to be present without indications of some degenerative conditions of the parenchymatous portions of the nerve fibers.

8. **Treatment of Pneumonia.**—M. Packard outlines the general rules and indications in the treatment of pneumonia. It is well to recall that each patient is a law unto himself, and each individual patient's blood pressure and vascular state probably differs in some degree. Some cases demand vasoconstrictors, such as camphor, caffeine, or suprarenal extract. Others demand only cardiac stimulation, and even a few demand venesection and vasodilatation. The combination of all methods may be required, but it is only by means of the intelligent study of the blood pressure and vascular state that better results can be realized in the treatment of pneumonia.

9. **Jequirity in Ophthalmic Work.**—J. Allan, in making use of this drug in ophthalmic practice has employed the infusion of jequirity in the strength of one in 12.5. The cases in which it has been prescribed were cases of granular conjunctivitis and corneal opacities. A requisite knowledge of what is expected to occur is very desirable, for to the uninitiated the intense reaction frequently provoked is somewhat alarming. It is also but right to inform the patients that in all probability the eye condition will temporarily become worse. Such a precaution will avoid much needless mental anxiety. The effect of the instillation of infusion of jequirity into the eye is to produce a marked inflammatory reaction of greater or less severity—the so-called "jequirity ophthalmia." There is generally severe conjunctival chemosis and there may be considerable edema of the lids. Such symptoms as intolerance to light, lacrymation, pain, etc., which are common to all acute in-

flammatory affections of the eye, are present. The acme of the inflammatory reaction is, as a rule, reached in from twelve to eighteen hours after the instillation, and the acute symptoms will have generally subsided in three or four days' time. The infusion of jequirity may have to be exhibited several times, but it is inadvisable to repeat the instillation until the acute symptoms have subsided. The interval between applications naturally depends to a large extent on the intensity of the reaction produced. Very often a further instillation of jequirity may be permissible after four days; in other cases an interval of a week or ten days must be allowed to elapse.

1. **Ligature and Suture Material.**—W. S. Halsted describes the use of silk sutures in the surgical clinic at Johns Hopkins University and points out the advantages of silk over catgut. Kocher has employed silk sutures to the exclusion of catgut for a number of years, it is true, but his example has not been generally followed. The author has given fair trial to sterilized catgut from time to time, but has found the ordinary black silk suture used by him much safer. The silk is finer than that used by Kocher (and black spool silk is selected in preference to white, because it is more easily seen, both on the bobbins and in the healed wounds), and the author relies on transfixion to prevent the ligature from slipping. With the finest silk and needles one can perform feats in hemostasis which would be very difficult if not impossible with catgut. The surgeon who has not tested the method will be surprised to find how large a vessel can be entrusted to a transfixion ligature of the finest silk. As regards later trouble from buried silk, the author believes the wound would not be infected once in a hundred cases when the technique is perfect. If fine silk is used and the infection is slight it is not probable that any of the buried threads will be extruded or the healing be delayed. At Johns Hopkins they find themselves more and more frequently employing the interrupted suture; a granny knot is adequate if fine silk is used, and in some cases even better than the reef knot. Fine silk often permits the closing of a wound that would require drainage if catgut were used. One should not use silk in the presence of infection. In many of their operations, and always when indicated, they paste to the skin over a wide field, a fine batiste dipped in celloidin. Since 1894 they have covered fresh wounds with silver foil and believe that it has an appreciable chemical effect, antiseptic, and not irritating. Three or four layers are usually placed on the closed incision and over this the thin paper between which the leaves are packed. Gutta-percha tissue is also found to be very useful. For thirty-three years gutta-percha tissue, usually referred to as rubber tissue or protective, has been one of the most prized and inexpensive articles of the author's surgical armamentarium. A moist scab under such tissue is better than a dry one, a fact of which any layman or surgeon can convince himself, and it is gratifying to see how generally gutta-percha tissue has come into use by American surgeons.

2. **Treatment of Diabetic Gangrene.**—De W. Stetten has evolved a method of conservative therapy based on the three following principles: (1) Systemic treatment of the diabetes and prophylaxis against the development of dangerous complications, especially coma. (2) An attempt to improve the circulation in the extremity. (3) The treatment of the local infection on rational general surgical and aseptic principles. Seventeen cases treated by this method during the past two and a half years are reported and analyzed: eleven of the patients were cured, five died, and one is reported not improved. The average duration of treatment was two and three-quarters months. The causes of death in the fatal cases were pneumonia, sepsis, and diabetic coma, either one of these alone or coma following the two others. Of the eleven patients who recovered, the routine treatment included in nine cases either no operative procedure at all, or such minor operations as opening an abscess or removal of a gangrenous toe. In the other two, on account of a rapidly advancing gangrene, amputation of the leg at the junction of the upper and middle thirds had to be performed. Each of these patients has a useful stump and a movable knee. While the number is not sufficient from which to draw a broad general conclusion, the author says that the cases were not selected ones and some of them were very severe and all of them would probably have been subjected to amputation under the former methods of treatment. The routine conservative treatment consisted of an antidiabetic regimen guided by daily examinations of the twenty-four-hour urine, the diet being relaxed only when coma was impending. The author regularly administers sodium bicarbonate in large doses (not, however, sufficiently large to derange the stomach), and codeine, and morphine to relieve pain. If anesthesia is required for operation chloroform should never be employed and ether should be used seldom if ever. Nitrous oxide or nitrous-oxide oxygen anesthesia is chosen instead. The attempt to improve the circulation of the extremities narrows itself down to the production of hyperemia by Bier's method which is of positive value. Passive hyperemia is contraindicated. On general principles the author administers sodium or potasium iodide for their absorbent qualities and nitroglycerin as an arterial dilator. There should be the strictest asepsis and the greatest attention to the needs of the individual case; antiseptics should be avoided as devitalizing, as well as tight bandaging, and the retention of pus must not be permitted to occur. As regards amputation when required, the author never uses an Esmarch bandage and the operation should be done as simply and rapidly as possible and with a minimum amount of traumatism.

3. **Advice to Surgical Patients.**—L. Freeman discusses the necessity for and the general character of advice which should be given patients on leaving the hospital after surgical operations. He notes the advantages of shortening the time that the patient is kept in the hospital after operation and the disadvantages which result from the passing of these patients from under the observation of the operator to follow their own ideas or the usually unreliable advice of those around them. The general instructions of the surgeon should explain the postoperative conditions to the patient in such manner as to remove all occasions for worry. Abdominal supporters, it should be explained, are of little service except to give a sense of security and comfort, and dressings are simply to protect the scar. The author gives special directions for overcoming constipation without becoming dependent on cathartics, and explains that the ordinary diet can, except in special cases, usually be resumed. With regard to exercise, going up and down stairs, returning to work, etc., he says that the tendency has been to keep the patient inactive and idle too long. But

the importance of rest and sleep and of not indulging in exhausting social duties, particularly in conversations about the operation, he emphasizes strongly. Explanation of several postoperative conditions which are to be expected will relieve the patient of much physical and mental strain and hasten complete recovery.

1. **Genital Functions of Ductless Glands in the Female.**—W. B. Bell states that any influence the ovary has over the general metabolism is related to and dependent on its primary reproductive function. The author does not believe that it influences the metabolism except in so far as this special function is concerned. Of course, removal of the ovaries may produce a temporary disturbance, but this does not invalidate the view just mentioned. On the other hand, the rest of the ductless gland system is related to the genital functions in various ways. Firstly, some of the members—the thyroid, pituitary, and suprarenals—influence the development and subsequently preserve the integrity and activity of the genitalia. Others—the thymus, and possibly the pineal—appear to prevent sexual precocity. Secondly, all the ductless glands control the metabolism in response to the necessities of the genital functions. But, in addition, they adapt the whole organism to the possibility of the situation, and regulate the secondary characteristics, both physical and psychical, to suit the needs of the individual. Once, however, the reproductive organs are removed or undergo atrophy, the primary genital functions of the rest of the ductless glands cease, and the rearrangement of the metabolism that follows produces what are known as the symptoms of the menopause. Contrariwise, insufficiency of the thyroid, pituitary, or suprarenals causes the cessation of the genital functions with atrophy of the uterus.

2. **Intrathoracic Aneurysm.**—F. de Havilland Hall concludes his lectures on this subject. The medical treatment comprises the use of one of the following methods: The Tufnell plan of treatment by means of a restricted diet consisting of ten ounces of solid and eight ounces of fluid food in the twenty-four hours. This diet is kept up for six or eight weeks, during which time the patient is kept at complete rest. The diet is then relaxed somewhat, but the absolute rest is continued for the next four months. This method of treatment relieves the symptoms of aneurysm, but it rarely produces a cure. The administration of iodide of potassium produces striking effects, chiefly in the relief of the pain of aneurysm. The gelatine plan of treatment was introduced by Lancereaux, who stated that among 1000 injections of a solution of gelatine he had not observed any mishaps. The solution he advised consists of 25 parts of gelatine and 7 parts of chloride of sodium dissolved in 1000 parts of water. He injected 200 grams at a time, and the process was repeated every four or five days. If the gelatine be of good quality and thoroughly sterilized at a high temperature Lancereaux maintained that the treatment is in no way dangerous, and yields very favorable results. The author next discusses the expectant and symptomatic methods of treatment. For the relief of the agonizing pain no remedy has a more remarkable effect than bleeding. The surgical treatment of intrathoracic aneurysm may be considered under five heads: (1) the ligature of the great vessels arising from the innominate artery or arch of the aorta; (2) the passing of wire—filipuncture—into the aneurysmal sac, with or without the passage of a galvanic current through the wire; (3) galvanopuncture; (4) Macewen's method of needling; and (5) the ligature of the neck of the aneurysmal sac.

4. **Tuberculosis in Infancy and Childhood.**—C. P. Lapage and W. Main state that the mortality from tuberculosis in children rises during the first year, reaches its maximum in the second year, and then falls rapidly. Statistics compiled from post-mortem examinations show that in childhood glandular tuberculosis is very common and in a fair proportion of the cases the disease is limited to the lymphatic glands (17 per cent. of the 150 cases). At the Manchester Children's Hospital the abdominal glands are more often affected than the thoracic glands in the ratio of 71 to 55. Though the abdominal glands are more often enlarged than the thoracic the most common condition is that in which both sets of glands are enlarged. Tuberculosis of the thoracic glands (28.1 per cent.) and of the abdominal (32 per cent.) may occur without any accompanying lesion of the lungs or intestine respectively. There may be disease of one part, such as the intestine or lung, with accompanying disease of both thoracic and abdominal glands. Apical tuberculosis is not very rare even in infants, and the form of pulmonary tuberculosis usually designated as chronic phthisis, though not very common, does occur in young children. Chronic cavitation is found even in young children, although in cases dying from chronic pulmonary tuberculosis there is usually a tendency for the disease to spread in the lungs and to become generalized to other parts of the body. Tuberculous meningitis most often follows generalized or miliary tuberculosis, but it not uncommonly occurs as a complication of glandular or bony tuberculous lesions.

6. Distilled Water versus Salvarsan in the Treatment of Syphilis. G. A. Stephens.
7. The Genital Functions of the Ductless Glands in the Female. W. Bell.

1. **Cancer of the Tongue and Its Relation to Syphilis.**—C. Ryall concludes on the basis of extensive observation that lingual cancer is a common sequela of syphilis, more common than locomotor ataxia and much more selective than the latter of the male sex. Its frequency with regard to sex is as 8 to 1, whilst the incidence of syphilis alone, judging from the author's experience at the London-Lock Hospital might roughly be considered as ten times more common in males than in females. The author lays down the following basic principles with reference to the treatment of lingual cancer: Wide removal in definite epithelioma; microscopic examination of suspicious lesions; the avoidance of tobacco by those who have syphilitic lesions of the tongue; and radical treatment of all syphilitics till serologically they are pronounced free. The thorough treatment of syphilis would wellnigh abolish cancer of the tongue.

6. **Distilled Water in the Treatment of Syphilis.**—G. A. Stephens recommends a simple treatment for syphilis that consists in the hypodermic injection of 6 to 10 centimeters of distilled water every three days for from two to four weeks. The rationale of this treatment is based upon the changes in surface tension of the body fluids produced by the injection of distilled water. The

lowering of surface tension is associated with a more rapid production of catalytic products in the cells, but the injection of vaccines is associated with the production of antibodies; therefore it seems to the author but right to infer that the production of antibodies is closely associated with a lowering of the surface tension. The addition of distilled water to blood corpuscles so affects the osmotic pressure as to cause a passage of water into the cell, which gets larger and eventually scatters its contents. In disease the rapid catalytic changes and the rapid production of antibodies are interdependent, and if one can induce these marked catalytic changes with or without a vaccine, one stands the chance of setting free a number of very useful and remedial antibodies. The marked effect produced by the injection of distilled water in two cases of cancer suggested to the author that in any similar disease of less malignancy their effect ought to be still better. The distilled water injections were given in six cases of syphilis with apparently remarkable results.

### Berliner klinische Wochenschrift.

*March* 31, 1913.

**Present Status of the Treatment of Syphilis.**—Touton goes back fifty years, when the Berliner klinische Wochenschrift was first established. At that period Lorinser and Hermann, two Viennese syphilographers, were loudly proclaiming that tertiary syphilis was a myth and that that which passed as such was only the pernicious effects of mercury. Even the great von Zeissl was infected by these views to the extent of claiming that the worst forms of tertiary syphilis resulted from early intensive mercurial treatment. He depended chiefly on small doses of iodides and Zittmann's decoction, using mercury only as a last resort. At the same period Boeck of Norway was treating his syphilitics by syphilization so-called, the supposed syphilis virus, with which he inoculated his patients consisting chiefly of the discharges from chancroids. Hunger cures were also practical. In great detail the author brings down his subject to date and says in conclusion that to-day the treatment of syphilis stands under favorable auspices. We have specifics and supporting remedies in abundance which may be varied indefinitely to meet the demands of the individual case. We must, however, fight a little shy of laboratory medicine in its direct transference to the clinic. Our greatest tasks are the prevention of latent focus formation and of mobilization of such foci once they have formed. We also have to antagonize vigorously the untoward collateral activities of our specifics.

**Present and Future of Spinal Cord Surgery.**—Rothmann concludes a serial article on this subject as follows: In addition to the older extramedullary spinal operations which have proved their worth, our resources will become enriched with the results of intramedullary operative intervention. This resource will have for its leading aim the extirpation of tumors of the cord whether generated from within or from without. When sufficiently small and circumscribed central tumors may be extirpated in one or two stages through the posterior columns, and lateral tumors through the lateral columns. The columns themselves are naturally sacrificed. The same technique may be used in foreign bodies (bullets, etc.), hemorrhages, foci of softening, cysts and abscesses. The author terms this pathologic intervention. What is termed by him physiologic intervention is also employed in the same connection. This is indicated to cut off the transmission of painful sensations and comprises division of the crossed anterolateral columns. The resource is indicated especially in inoperable tumors. Division of the posterior columns for spastic states is inferior to Foerster's nerve root division, but is of benefit in athetosis.

**Ulcus Duodeni in the Nursling.**—Schmidt states that this subject has been much neglected. This cannot be due to the rarity of incidence for the association is one relatively common and is recognized as an occasional associate of pedatrophy. The author reports a number of cases and his conclusions are as follows: Round ulcer of the duodenum occurs with greater frequency during the first year of life than is commonly assumed. Of 3,824 autopsies made during the past seven years under Professor Ponfick this lesion is shown to occur more frequently during this year than in any subsequent one. Of 1,109 autopsies during the period of childhood 20 cases (1.8 per cent.) were examples of ulcus duodemi in the nursling. It appears to be due to any condition which greatly weakens the vitality—prolonged suppuration, sepsis, rachitis, nephritis, and primary marasmus.

### Münchener medizinische Wochenschrift.

*April* 1, 1913.

**Serodiagnosis of Pregnancy, etc.**—No less than five communications on this subject are published in this number. Schlimpert and Hendry at Krönig's Freiburg clinic relate their experience with the dialysis procedure and ninhydrin reaction. Their conclusions are in the highest degree corroborative of those of Abderhalden himself. There was not a single negative find. Unfavorable results reported by others are referred to defective technique and failure to study controls. The ninhydrin reaction is a specific one almost without exception. Freund and Brahm discuss the optical and dialysis methods which they have tested in Charité Hospital, Berlin. They write at much length and submit numerous tabulated results. The conclusions are not so optimistic as to what has actually been done, although they are hopeful of ultimate success. Negative results occur with the most perfect technique and from positive finds we cannot yet with certainty diagnosticate pregnancy. The discovery of these reactions marks, however, a notable biologic advance. Professor Freund gives a brief outline of the history of the serodiagnosis of pregnancy. The first step in this direction was the discovery of a precipitin reaction by Liepmann in 1902 in which placental serum was employed. The latter, while prepared by treating animals with placental extract, gave positive results in gravidæ, negative in nonpregnant women and males. Other labors resulted in this field and Abderhalden's methods published in 1909 were the direct outgrowth of these antecedent studies. Freund does not write in the interest of a priority claim, but simply to demonstrate the evolution of serodiagnosis. Abderhalden, however, answers him at length, denying that his discoveries came about in the manner stated. He goes back further to the publication by Schmorl and Veit of the discovery that placental tissue finds its way into the blood of the gravida. This alone is the foundation of his studies.

**Advances in Our Knowledge of Beriberi.**—Wieland, at the close of a collective review of recent papers on this subject, expresses himself as follows: Let us suppose that people who subsist chiefly on polished rice are deprived in part of some substance necessary to their vitality, and that the nutritive defects may be corrected by eating whole rice, or by the simple injection of the more or less hypothetical protein substance "vitamin," "oryzarin," "antiberiberin," or whatever else we may term it. Animal experiment gives strong evidence in favor of this view, and numerous clinical results also point in the same direction. It is, however, quite probable that the carbohydrates may be similarly defective. Table sugar is practically chemically pure and cooking starch not less so. Again we know that prolonged boiling quickly destroys vitamin. What the author seeks to bring out is that beriberi is not a unique affection, but simply a member of a group disease which is due to defective nutriment.

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### ELEMENTARY PRINCIPLES OF LIFE INSURANCE.

*The Reserve.*—It may be accepted that no part of the subject of the principles of life insurance is more generally misunderstood by the public and by the policyholders than that of the purpose of the reserve fund. Certain uninformed policyholders have become agitated over the proportions of this fund, even to the extent of appealing to the courts for an order to compel the companies to distribute immediately to them that part of the reserve fund which they believed to belong to them as individuals. It is apparent to the initiated, however, that the stability of the companies and the certainty that they will be able to carry out their contracts to the very end depend upon the maintenance of an adequate reserve, the matter being such an important one in fact, that the laws of the different states require the companies to keep a specified reserve on hand at all times.

It would be possible to effect insurance at lower rates increasing year by year, if this were a convenient and practical plan; but it has proved eminently more satisfactory to charge a uniform level premium throughout life. The disadvantages of the plan of insuring with increasing rates is demonstrated by the experience of the assessment companies, which shows that men dislike the idea of rates which, though low in the beginning, gradually become so high in advanced age as to be prohibitive. This unsatisfactory feature would also upset the calculations based on mortality tables and result in an impairment of the financial condition of the companies, as it would lead to the withdrawal of good risks, while those with impairments would surely remain.

The level premium plan, then, is the only one which can be carried out on a certain and scientific basis. In order to accomplish this end, the net premiums charged in the early years must be greater than are necessary to cover the risks in these years, and the excess derived in this way must be reserved for the later years when the advancing age of the insured will bring with it a rate of mortality higher than could be met by the net premiums payable at this time.

To the uninitiated the reserve accumulated as a result of the low early mortality seems enormous and uncalled for, but it must always be understood that it is put by purely for the purpose of paying death claims for which it will positively be needed later on. Another point to be borne in mind is the influence of modern conditions of living which tends to the lowering of the mortality among insurers in early and middle life and to a decidedly increasing mortality among those in older ages. The saving in mortality may therefore be expected to be smaller in the advanced ages when the death rate will more nearly approach that indicated in the table.

The insurance fund is created solely from and, moreover, includes the entire amount of the net premium receipts with the interest thereon at the assumed rate, and the reserve is the balance of this fund on hand at any given time. It belongs to the policyholders as a body, not as individuals, for it has been put by solely for the payment of death claims and it must constantly be drawn upon for that purpose up to the consummation of the last contracts, when none of it will remain. Technically speaking, the reserve which the company must have on hand to meet the future claims as they become due is the difference between the present value of the claims which under the existing policies the company will have to meet and the present value of the payments under the existing policies which the company is going to receive.

The source and purpose of the reserve may be made more clear by a few extracts from the standard tables compiled by the companies for ready reference. In the first place it must be explained that the net premium of $19.91 already referred to is the amount actually collected in practice, but that the exact net premium is $19.90726. In calculating the reserve, the fractional part of a cent must be taken into consideration on account of the great size of the total fund. In this way, a larger amount is collected than is absolutely necessary but the difference gained by the companies will be returned subsequently to the policyholders in the form of dividends.

If the 81,822 members, age thirty-five, of the hypothetical company insuring for $1,000 on the ordinary life plan, pay $19.90726 at the beginning of the first year, the net premium income for the first year will be $1,628,851.83. To this is added twelve months' interest at three and one-half per cent. ($57,009.81), making a total income in the first year of $1,685,861.64. The mortality table shows that 732 deaths may be expected during this year calling for the payment of claims amounting to $732,000. Deducting these claims from the total income, leaves a balance of $953,861.64, the total insurance fund or reserve for this year.

There will be 81,090 persons living at the age of thirty-six at the beginning of the second policy year. Each again pays a premium of $19.90726, making the total premium income for this year amount to $1,614,279.71. Adding to this the reserve from the first year ($953,861.64) there will be a balance of $2,568,141.35 at the beginning of the second year, and the interest ($89,884.95) will bring the total insurance fund at the end of the second year to $2,658,026.30. Deducting the death losses expected this year to the amount of $737,000, there remains a balance of $1,921,026.30.

It is seen, then, that the reserve increases during the early years of the policies, but if these calculations are followed out year by year, it will be found that by the time the age of fifty-seven is reached, the death claims begin to exceed the premium receipts, and that eight years later at the age of sixty-five the yearly mortality is twice the premium income. Finally, if the computation is carried on until the three surviving policyholders at age ninety-five are reached, it will be found that the net premium income in that year is only $59.72. To this, however, is added the reserve carried from the previous year ($2,838.85) and also the interest of one year ($101.43), so that the total fund on hand at the end of the year amounts to $3,000, just enough to pay the last three claims. With the last three payments the hypothetical company may terminate, having fulfilled the requirements of every contract through the accumulation of an adequate reserve and without depending upon the taking in of new members, that is to say, the so-called infusion of "new blood."

# Book Reviews.

Diet and Hygiene in Diseases of the Skin. By L. Duncan Bulkley, A.M., M.D. Physician to the New York Skin and Cancer Hospital; Consulting Physician to the New York Hospital; Consulting Dermatologist to Randall's Island Hospital, to the Hospital for Ruptured and Crippled, and to the Manhattan Eye and Ear Hospital. Price, $2.00 net. New York: Paul B. Hoeber, 1913.

The subject of metabolism is looming large in medical thought and practice in these days, threatening even to outrank that of bacteriology, which so overshadowed every other idea but a few years ago. The disease was simply a struggle between toxin and antitoxin, the body and tissues being merely the battlefield; but now it is coming to be recognized that the nature of this field is of the utmost importance. If the invading hosts of bacteria find therein sustenance for even a brief period, the battle is lost. Whether the body does or does not offer a favorable soil for the growth of pathogenic bacteria depends largely upon wherewithal it is nourished and how it assimilates its nourishment. And other diseases and conditions predisposing to disease depend likewise upon the processes of metabolism. Obesity, gout, diabetes, blood pressure, Bright's disease are all largely diseases of metabolism. It is believed by an increasing number that the problem of cancer will be solved through the study of metabolism, and in the book before us Dr. Bulkley argues most convincingly that the origin and cause of very many of the common diseases of the skin are dependent upon or largely influenced by the nature of the food taken. The author's statements are based upon his personal experience in a long series of cases and it is difficult to see how one, after reading this book, can doubt that a purim-free diet is best suited for the nourishment of man, or at least that many of the physical ills that afflict mankind are caused by an excessive intake of proteins. Dr. Bulkley's book will be hailed by the followers of Haig as one more, and a strong argument in support of their contentions.

Lectures on Clinical Psychiatry. By Dr. Emil Kraepelin, Professor of Psychiatry in the University of Munich. Authorized Translation from the Second German Edition. Revised and Edited by Thomas Johnstone, M.D., Edin. M.R., C.P., Lond.; Member of the Medico-Psychological Association of Great Britain and Ireland; Fellow of the Royal Medical Society; Fellow of the Incorporated Society of Medical Officers of Health, and Member of the Leeds and West Riding Medico-Chirurgical Society. Third English Edition. Price $3.50 net. New York: William Wood & Company, 1913.

Kraepelin is recognized as the greatest authority in psychiatry at the present day. Everything he writes is read by psychiaters in this country with avidity. His clinical lectures on psychiatry have passed through two editions in German and the present is the third edition in English. These lectures are practical for the general practitioner as well as for the specialist. In them the question of diagnosis occupies, to be sure, the first place; but the subject of treatment is nowhere ignored. The latter statement is especially true respecting the acute exhaustive conditions. The author remarks, however, in his preface, that the lectures must not be looked upon as a text-book. Their aim, he says, will be far better attained if they prove of some value as a guide to the clinical investigation of the insane. In his opinion, "what the student ought to learn in the hospital, besides the examination of patients, is not text-book knowledge, which he can acquire just as well or better at home, but how to turn his observations to account, and the careful judgment of any given case." So, while the present work is lacking in the actual presentation of patients, such as one can only get in hospital experience, yet the material utilized in the author's descriptions is worked up in a manner which only the master can carry out. The descriptions are brief and yet fairly complete; and they are systematic. There are thirty-two lectures, in the present edition, embracing a great variety of the psychoses of the Kraepelin classification, or pertaining to the various forms. The editor has also brought the subject matter up to date as far as he could, by appendices. The translation is in pleasing style and seems to have been well performed. Some corrections have been made to the former English editions. Chapters which might be cited as of especial interest to the general practitioner are those on epileptic insanity, alcoholic mental disturbances, insanity in acute diseases, varieties of delirium, puerperal insanity, morphinism and cocainism, morbid personalities, morbid criminals and vagabonds. But there are so many others of equal interest, such as hysterical insanity, insanity after injuries to the head, irrepressible ideas and irresistible fears, that one is tempted to quote the entire list of chapter headings to cover those which will be found of real interest and value in the book.

The Treatment of Infantile Paralysis. By Oskar Vulpius, M.D., Professor Extraordinary at the University of Heidelberg. Translated by Alan H. Todd, M.B., B.S., B.Sc. (Lond.), House Surgeon, Grey's Hospital; Late Resident Surgical Officer, Royal National Orthopedic Hospital. With Introduction by J. Jackson Clarke, M.B., (Lond.), F.R.C.S. Price $4.00 net. New York: William Wood & Company, 1912.

The rapid increase and wide dissemination of poliomyelitis during the past few years has increased the responsibility of the physician and especially of the orthopedic surgeon in the treatment of this disease and its aftermath. In spite of the most painstaking care in the management of the initial phase of this disease, in the majority of cases the skill of the orthopedic surgeon is ultimately taxed in the management of the resulting paralyses and deformities. The attitude toward the latter in the past has been one rather of passive resignation, with the application of plaster-of-Paris dressings or of braces, with the object of preventing contractures or strengthening weak limbs. Within recent years the resources of active surgical intervention have been freely drawn upon, and the methods of tendon transplantation and shortening, of arthrodesis, etc., have enabled the orthopedic surgeon to accomplish a great deal for the unfortunate victim of infantile paralysis. The utility of these methods has been abundantly tested in the University Clinic of Professor Vulpius at Heidelberg, who brings to the writing of this book the credentials of authority and of experience. The volume deals almost exclusively with the orthopedic aspects of infantile paralysis. Nevertheless, an introductory chapter discusses the symptomatology, etiology, and pathological anatomy of this disease. Part I takes up the general principles of the orthopedic management of cases of poliomyelitis under the following subdivisions: (1) General treatment in the acute stage, and stage of repair during the first year of illness. (2) Orthopedic apparatus. (3) The surgery of paralysis, including the treatment of paralytic contractures and deformities by means of "redressement," tendon lengthening, and tenotomy, and the restoration of function, by means of muscle implantation, arthrodesis, tendon shortening or transplantation, and nerve transplantation. Part II deals with the special regions of the body with their paralyses, such as the neck with its paralytic torticollis, the back, with its paralytic kyphosis, lordosis, scoliosis, etc. One is impressed in reading this volume with the wealth of clinical material upon which it is based. This material is clearly mirrored in the large number of photographic illustrations which form a valuable and most striking feature of this work. The surgery of paralysis is discussed with that wonderful elaboration and regard for details which is characteristic of German authors. This is a part of the work in which the orthopedic surgeon will find many valuable suggestions. There are many diagrams showing the modes of dividing and uniting tendons. The use of silk ligaments and the technique of making them are discussed in detail. The author, however, does not favor the systematic employment of silk ligaments, except as a means of facilitating the periosteal fixation of natural tendons. The subject of nerve transplantation is thoroughly discussed in a section of thirty-three pages. The author believes that nerve transplantation attacks the disease at its actual site, and if successful is an ideal method of treatment, for it brings about functional recovery without anatomical disturbance of the musculature. But neuroplasty is not of such practical value as tendon transplantation for the large run of hospital patients, and is less certain in its results. In presenting this book to English readers, the translator has performed his task with a sympathetic appreciation of the importance of the subject matter and a command of clear and elegant diction. The volume is one which may be regarded as a landmark in the literature of poliomyelitis.

The Story of a Doctor's Telephone—Told by His Wife. By Ellen M. Firebaugh. Author of "The Physician's Wife." Price $1.25. Boston, Mass.: The Roxbury Publishing Company, 1912.

This story gives in a bright and original way all sorts of incidents that go to make up human existence. They are all so typical and so true to life that they can be duplicated in any physician's household. It is worth an hour of the busy doctor's time to be able to laugh at his own little annoyances and troubles, as this story will compel him to do. The author has a keen sense of humor and the more serious incidents are treated with the truly sympathetic touch. Whether or not the doctor reads the story may not be important, but it is to be hoped that all his patients will do so.

## THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held March 24, 1913.*

The President, Dr. Brooks H. Wells, in the Chair.

**The Problem of Cancer.**—Dr. Francis Carter Wood read this paper. He said that the cancer problem was still absolutely baffling despite the work of clinicians for generations and there was little hope of an immediate solution. From whatever direction the question of cancer was approached the fundamental problem was simple; it was only why one cell grew without obeying the observed rules limiting tissue proliferation in adults, while others did not. Inversely, an equally important and difficult question was why the normal adult cells did not grow wild, but remained within very fixed anatomical regions. The final etiological question was, therefore, why a cell grew—a problem at the present time insoluble, and likely to remain so. A survey of the results of morphological investigation of human cancer showed that the classification of the different types of cancer had been perfected and elaborated until but little more could be expected. This had enabled them to determine rapidly and accurately the nature of tumors removed at operation and even to assist the surgeon in determining the nature of the growth before deciding as to the extent of any operative procedure. The questions as to whether cancer was hereditary and whether it was on the increase were impossible to answer at present as even in a great city like New York the imperfect forms of registration did not permit of an accurate classification of the nature of the tumor reported, of the organ involved, the sex of the patient, or other necessary data for any practical cordination of statistics. The limits of research in this direction had been reached until health records were much improved. The author said that it seemed to him that the only way in which the problem could be solved was by studying the cell and the influences which acted upon it and then endeavoring to elucidate the conditions by which cells could be modified so that they grew beyond their natural anatomical bounds and became cancers, the human race being considered as only one animal type and its cancers as a special variety of mammalian cancer. But centuries might elapse before an insight was gained into these obscure phases of life and it would be unwise to center wholly upon this purely biological phase of the question because they cared little for the cancers of mice and rats except as they helped to interpret the cancers of man. Hence observers should try out on inoperable cancers in human beings every hint which analogy might offer as suggesting a possible means of obtaining immunity against cells, using the knowledge now available as to the way in which bacteria attacked the organism. If the discovery of fundamental principles lay in the direction of human experimentation rather than along lines of clinical observation, it might be interesting to review the results of experimental work during the last twenty years. But in doing this it was important to remember several facts which were usually not taken into consideration. First, distinct biological differences were apparent between carcinoma and sarcoma and in all discussions of the cancer problem sharp distinctions should be made between results obtained on the different groups, and, second, most of the work that had been done had been on transplanted tumors which were much more susceptible to external agents than were primary tumors. With these restrictions it might be regarded as proved: 1. That carcinoma in animals was not contagious. 2. That carcinoma in animals was not due to a parasite. 3. That the morphology of carcinoma throughout a long series of propagations remained much the same. 4. That in the transplantation of carcinoma from one animal to another the new tumor was produced entirely from the cells transplanted and no transplantation would occur if the cells were crushed or their individuality in any way destroyed. 5. That occasionally in the course of transplantation of a carcinoma change might be induced in the connective tissue elements of either the stroma of the tumor or what was more likely, the connective tissue of the animal in which the new tumor developed, so that a sarcoma was produced that might overgrow the carcinomatous portion and the resulting tumor continue as a pure sarcoma. This coincided with the phenomenon occasionally seen in human beings where a mixed carcinoma and sarcoma existed together. It was suggestive that in metastases from some of the teratoma both the sarcomatous and carcinomatous elements or either formed alone might metastasize. 6. That the microscopical structure of a tumor was no certain guide to its malignancy. With certain reservations this applied quite as well to human beings. Mechanical conditions seemed to play just as important a part in the malignancy of a tumor as its purely morphological cell structure. 7. That there was a very marked difference in susceptibility to tumor inoculation in animals of the same species under different conditions of stock, climate, and nutrition. This showed how delicate was the balance between the tumor and the host and gave a reasonable basis for hope that by modifications of living the incidence of carcinoma might be somewhat diminished. 8. That it was impossible to transfer tumors from one species of animal to another. 9. That apparently no general immune reaction to carcinoma was procured in the fluids of the body, that was, when live cancer cells were introduced into an animal they did not act as did bacterial or foreign proteins, by the production of antibodies, but that healing, if it occurred, was due to local tissue resistance. 10. Finally it had been shown that autolytic products or the expressed juices or crushed or ground cells of tumors had no capacity to induce immunity to carcinoma in an animal, but, on the contrary, such material might often produce an increased sensitiveness to tumor growth. Only growing uninjured cells had the capacity to induce immunity and this immunizing power was inherent not only in the tumor cells but also in the normal tissue cells, such as blood corpuscles or the cells of the skin, liver, kidney, or spleen, from animals of the same species. The remarkable effect of radium on transplanted mouse tumors had led to the abuse of this form of treatment. Animal experiments had also justified the criticism of the cures reported from the use of vaccines, from the employment of bacterial products, and from certain chemotherapeutic attempts. It seemed that the lines of attack for the future were for the biologist to learn as much as possible of the methods of influencing the growth of the normal cell. Work of the character which Jacques Loeb had carried on for years on the eggs of sea-urchins pointed clearly to the mastery of the question. The experimental pathologist had before him the somewhat appalling task of repeating the experiments of Murray in breeding tumor mice for six or eight years, through hundreds of generations, in order to determine whether the slight hereditary liability which Murray observed was generally applicable in different strains of these animals and in other animals, provided they could obtain a sufficient number of spontaneous tumors. Veterinary surgeons could do much to help out the pathologist if they would make a more thorough study of tumors in dogs so that they could get an inoculable carcinoma of these animals, the larger size and longer life of which would be much more suitable for certain types of experiments than were mice and rats. The question of the nature of immunity following the inoculation of living cells must be re-examined with the greatest care. The serologist must be called in to settle the disputed question of serum reactions following the inoculation of living cells and the question of the presence or absence of immune substances in the blood. The discovery by Rous that a type of sarcoma in one animal alone seemed to possess a filterable virus pointed to an extensive line of work on the sarcomata, for while carcinoma was, according to their present knowledge, not due to any parasitic agent, yet a certain group of sarcomata had always been considered by pathologists as probably of parasitic nature. The chemists had still much to do in the study of the nature and activities of the ferments, not only of the healthy normal cell, but also of the cancer cell, and even the fundamental problem of whether the metabolism of the cancer cell was different from that of the normal cell could not yet be regarded as finally settled, though many suggestive observations pointed to a distinct difference in this respect. The pharmacologist might well take up the hint of Ehrlich's salvarsan and Wassermann's selenium-eosin, and attempt to produce some substance which would have a direct chemical action on the cells of the carcinoma without destroying the life of the host. Even the physicist might help by separating for use some of the special products of the disintegration of the radiocative bodies so that they might be applied directly to tumors in a concentration much greater than hitherto available. The clinical pathologist and the practitioner of surgery had an important field in that methods of diagnosis were still too imperfect in the determination of internal tumors. The field of the surgeon would be greatly increased if the clinical laboratory man could present him with a means for early and certain diagnosis. The knowledge should be spread that at the present time the surgeon had the only efficient means of treating carcinoma.

**The Surgical Pathology of Cancer.**—Dr. Thomas S.

Cullen of Baltimore, Md., read this paper. He emphasized the importance of cooperation between the laboratory man and the surgeon and believed that in the future all surgeons would be trained laboratory man. In abdominal surgey, if the surgeon was familiar with his pathology, it would give him a clew to the work he was called upon to do. While many investigators were trying to discover the cause of cancer, there were many others who were trying to get at an early diagnosis because no matter what the cause might be the cure of the patient depended to a large extent upon the early diagnosis. After briefly reviewing some of the chief varieties of cancer, Dr. Cullen said that in regard to cancer of the tongue it had been pointed out that the milky patches on the tongues of smokers, if removed at once, would result in no further trouble; if one waited without interference carcinoma would develop. In carcinoma of the lip, if the radical operation was performed, the chances of complete cure were good. In carcinoma of the stomach pathology did not aid one a great deal. If one waited for the stomach washings of the characteristic lesions to make a diagnosis of cancer of the stomach it would be so late in the course of the disease that little could be done for the patient. The only thing to do was to make an exploratory operation in order to learn with what kind of a cancer one had to deal. The surgeon as well as the pathologist was aided by a fluoroscopic examination and this was destined to play a large rôle in the making of early diagnoses. If one were dealing with a carcinoma of the intestine, signs of obstruction appeared fairly early and more and more cases were now apparently cured by early operation. The pathology here was quite characteristic. Cancer of the rectum and lower sigmoid could be detected by the proctoscope, and by its use many early diagnoses were now made. In fact, with the proctoscope in the majority of cases a diagnosis was relatively easy. There were two chief growths of cancer which were very important, cancer of the breast and cancer of the uterus. Cancer of the breast in the early stages might be beneath the skin and there might not be any adhesions or puckerings, but as the disease advanced this characteristic puckering of the skin occurred. If one cut into the growth and removed a local area, the portion could be immediately recognized; if it proved to be cancerous, the complete and radical operation should be done together with the removal of the axillary glands. Dr. Cullen discussed the surgical pathology of the uterus and exhibited histological pictures on the screen showing what was normal and what was pathological. In cases of cancer of the uterus the pathologist acted as the Supreme Court and decided whether or not cancer existed, and it depended upon him whether or not the patient was to be subjected to a dangerous operation. There was the closest relation between the laboratory man and the surgeon, as had been pointed out, and it was fortunate if the two were combined in one man. Pictures were shown of normal and pathological conditions of the cervix and uterine mucosa. In connection with the differential diagnosis between carcinoma and other conditions of the uterine mucosa Dr. Cullen showed pictures of hypertrophy of the uterine gland in both the pregnant and non-pregnant uterus, the manner in which new glands were formed in adenocarcinoma, atypical proliferation of the gland epithelium, commencing carcinoma of the body, etc.

**The General Principles of the Surgical Treatment of Cancer.**—Dr. John A. Hartwell presented this paper. He said that the hope that the experimental studies now being so extensively carried on would result in some means other than surgical for the treatment of cancer must not be permitted to obscure the fact that at the present time the only treatment which was effective was an operative procedure. The degree of effectiveness which this treatment yielded was based on well-defined principles and it was with these that they were concerned. The fact of prime importance was that, in its incipiency, cancer was a local lesion. In the early stages the growth was entirely by continuity. Hence there must be a time in the life history of every cancer when it was amenable to complete eradication, unless it was located in a region where its inaccessibility rendered this technically impossible. It followed sooner or later when the disease ceased to be a localized lesion that its eradication was not a possibility. Fortunately cancer attacked with the greatest frequency the stomach, the uterus, the rectum, the large and small intestines, the female breast, and the structures in and around the mouth, and in about the order named as regarded frequency. Cancer was comparatively rare as a primary lesion in the pancreas, liver, brain, and lung. Thus in the majority of cases cancer occurred in an accessible region, and patients suffering from it had been sucessfully cured when the lesions had been located in any of these regions. While surgery afforded a cure in a large number of cases, the death rate from this disease was enormous and apparently on the increase. The reasons for this were ignorance, carelessness on the part of the medical profession and the laity, the inherent difficulties in diagnosis, and the fact that surgery had as yet much to learn concerning the overcoming of the difficulties which surrounded the complete eradication of the disease even in the early stages. The Pennsylvania Cancer Commission in an investigation of four hundred cases reported from individual physicians throughout the State, found that superficial cancer had been apparent on an average of eighteen months before the case came to the surgeon. Eleven months had elapsed between the time that a surgeon had been consulted and the date of the operation. In deep cancers this time was one year. About one case in thirty of breast cancer was not even examined by the first physician consulted, and in one case in six, salves, ointments, etc., were prescribed with advice to temporize. Sixty-eight per cent. only of superficial cancers were operable when they came to the surgeon. Only 48 per cent. of deep-seated cancers were operable when first seen by the surgeon. Data from the large hospitals of New York City showed that this community was equally open to criticism. In a series of cases covering five years in one hospital over 63 per cent. were found totally inoperable. Of 102 cases of pyloric cancer admitted to the hospital during a period of five years, only three were successfully treated by the radical removal of the disease, and what was worse only ten were in condition to attempt such treatment. Dr. Hartwell related several cases that illustrated the direful results of a waiting policy in cases of cancer of the pylorus. He related one instance that had come under his personal observation in which the patient showed symptoms of serious gastric disturbance with loss of weight; these symptoms were assigned to a gastric neurosis due to overwork. He was advised to take a long rest, preferably taveling abroad. Less than a week later, just prior to his expected sailing, he developed acute abdominal symptoms for which an immediate operation was necessary. An inoperable carcinoma of the pylorus was found. There was no justification in thus temporizing with a disease that inevitably proved fatal if left alone. Every patient presenting symptoms which made the diagnosis of a deep-seated cancer seriously to be considered was entitled to and should have urged upon him an exploratory operation. Dr. Hartwell gave the results of gastrectomy in the hands of different operators which showed that the mortality and percentage of recurrences were such as to make it little less than criminal that in this city only one patient out of thirty having gastric cancer, admitted to a general hospital, reached the surgeon's care early enough to allow of his being permanently helped. The causes at work to produce such a state of affairs were the difficulties in diagnosis, carelessness and a spirit of *laissez faire*, which meant that laziness and possibly ignorance were potent factors in maintaining the high mortality of cancer. The campaign against cancer must be energetic and continuous and directed toward an improved condition of affairs in their own ranks. The principle of all importance was based on the fact that cancer was at first a local disease and was then curable, while later it was neither. Therefore he made an emphatic appeal for the exercise of every diagnostic aid, including exploratory operation if need be, for its early recognition. A second principle of hardly less importance rested on the fact that certain lesions might be transformed from a benign to a malignant character. The Pennsylvania Commission found that 40 per cent. of the deep-seated and 39 per cent. of superficial cancer could be so considered. Notable examples of these were seen in the leucoplakia of the tongue, the chronic ulcer on the lip, the pigmented mole, the chronic pyloric ulcer, the clonic diverticulum, and possibly most important of all the chronic cystic mastitis. The experience of every surgeon and pathologist proved to his own satisfaction that these conditions had changed from a benign to a malignant growth. Why, then, were they persistently treated as the former until the latter had developed? If the physican would learn this pathological lesson and explain to the patient that surgery in a much more dreadful form was the outcome of the waiting policy, the affirmation might be ventured that a much larger number than at present would elect to have the early operation. In many instances a precancerous condition existed and the term, with a definite knowledge of its significance, should become one in general daily use by the clinician. The knowledge of the relative frequency of the different varieties of cancer was meager and this paucity could be remedied by properly organized study. Cancer cells were active entities with great potential evil, and hence should be

treated in such a way as to limit their extent when once they had found a place in the human body. The operative principles which must guide the surgeon in the management of cancer were based on the fact that the tumor followed in individual localities definite lines, and on the fact that cancer cells had an inherent vitality which made them capable of independent growth when planted in a favorable environment. Experience had taught what directions would be taken, but there was still a dearth of knowledge as to which type of tumor was most active in rapid and wide dissemination.

**How We May Reduce the Mortality from Cancer of the Uterus.**—Dr. Herman J. Boldt presented this paper. He concluded that nothing definite was known as to the cause of cancer and that there were no symptoms which alone were characteristic of cancer of the uterus. The onset of the disease was so insidious that sometimes the neoplasm had progressed to a stage beyond the hope of cure by any kind of operation before the appearance of a symptom sufficiently marked to cause the patient to seek advice. As to the question of publicity, the general sentiment had been that knowledge of the early symptoms of cancer of the uterus should be disseminated through the medium of the newspapers and magazines. So strongly was this emphasized on a number of occasions that at the Congress of Surgeons of North America, recently held in this city, a committee was appointed to devise a method of securing such publicity. If publications were to appear in the lay press, the method recommended by the committee of the American Medical Association was the only one that was strictly ethical. The printing of articles with the name of the medical writer attached was reprehensible. In the publicity undertaking they were following in the steps of Germany where the dissemination of knowledge by similar means was begun by Dührssen of Berlin many years ago. While abroad during the past summer the writer had consulted with a number of men who were connected with university hospitals and who had studied carefully the question of publicity. They stated that they had seen no larger percentage of operable cases since circular letters had been sent out but what they had observed was that a goodly number of neurasthenic women were made more nervous and consulted physicians in the fear of cancer. They were not likely to get under observation a larger number of cases of incipient cancer of the uterus by giving the cancer symptoms to the public through the medium of the lay press. On the contrary, it was more than likely that of the large number of women suffering from leucorrhea, those of the neurasthenic type would simply acquire an aggravation of their nervousness with the result that they would rush to the physicians for examination, and if told that they had no malignant disease would be distrustful and seek the advice of others. The only rational way was to impress on the profession the importance of being conscientious in the manner of examination, and never superficial. Let the teaching to the laity on this particular subject come from the family physician and not through newspapers and magazines. To bring about a lower mortality from cancer of the uterus it was only necessary that members of the medical profession should use in practice what they so well knew in theory concerning the occurrence of the first symptoms of this dread disease. The physician must be urged to realize that in all instances in which there was the slightest suspicion of cancer his obligation was to ascertain by all diagnostic means at his command that cancer was not present rather than to affirm a cancer diagnosis. Of every curetting scrapings should be examined. From every cervix that appeared suspicious of cancer enough should be excised for a microscopic examination. When the diagnosis of cancer had not been positively excluded such a patient should be constantly under the supervision of her physician. Where a diagnosis of cancer had been made the writer favored the extended abdominal operation for the greater number of patients. The exceptions to this rule were patients who were very obese; cases of cancer of the body of the uterus, where the uterus was freely movable, and cases of incipient epithelioma of the vaginal part of the cervix. Patients who had passed what the writer had designated as the incipient stage of cancer should be operated on by the abdominal route, and the operation should be done extensively; the parametrium and enlarged glands should also be removed. The ordinary panhysterectomy was inadequate. On women who were so obese that an abdominal operation was undesirable, the vaginal operation devised by Schauta in connection with the paravaginal section described by Schuscardt, should be the method of choice. Borderline cases, those in which it was very doubtful whether it would be found possible to extirpate all the cancerous tissue although it might be possible to extirpate the uterus, were not suitable for the extended abdominal operation since the primary mortality was necessarily great and the remote results were comparatively still more unfavorable. In these patients a palliative operation with an actual cautery was better. Dr. Boldt stated that, although he had subjected a number of patients to *x*-ray treatment for cancer of the uterus, he had not seen an instance of marked benefit. He reviewed the case reported by Bumm of a woman with an absolutely inoperable cancer who was much improved by the *x*-ray treatment, the cancer showing such a degree of retrogression that operation became possible. This case was interesting because in spite of the excellent clinical result microscopical examination showed the cervical wound cavity lined everywhere by a thin, not visibly changed, layer of proliferating cancerous tissue, then by a layer of strongly celled infiltrated tissue and finally by a voluminous layer of sclerosed connective tissue which almost entirely superseded the muscle lamellæ. In the parametrium and even outside the callous cancer nests were found. Frequently reports had been published of inoperable cases of cancer which had been rendered operable by *x*-ray therapy. Why were these patients operated upon when improvement was evident? Might it not have been that a continuance of the treatment would have resulted in a cure? Dr. Boldt urged that in this class of patients when an inoperable cancer became operable that the treatment be continued and the results noted.

**The Problem in Local Recurrent Breast Cancer.**—Dr. Carl M. Strobell of Rutland, Vt., read this paper. He said that this contribution to the present symposium was based on a contribution to the *American Journal of Surgery*, November 19, 1912, entitled, "A New Method of Treatment of Cancer of the Breast Based on the Nature and Causes of Recurrence." Little appeared in the literature on the subject of recurrence except the reports of unsuccessful cases. Dr. Strobell showed that the embryonic theory of the etiology of cancer was untenable and expressed the conviction that cancer was due to a pathogenic germ infection. Whenever a metastasis to any part of the abdominal or pelvic viscera manifested itself prior to or coincident with the recurrence it was evident that the primary operation was too late. Today for the first time in medical history there was apparently something tangible upon which to hang one's hopes, and this consisted mainly of the very obvious fact of infection by a specific pathogenic cancer germ, and the apparently corroborative results of the new chemic surgery. By the employment of the technique described in the article above referred to, recurrence unaccompanied by internal metastasis, was a curable condition. As an object lesson of what the method would do the author reported the case of a patient and presented illustrative photographs taken at different times during the progress of the operation and afterward showing the excellent results obtained. The patient had a very extensive recurrent cancer of the breast, one in which a surgeon would be loathe to attempt a re-excision. A radical standard extirpation of the breast had been performed in 1910 and at the end of a year and three months recurrence was noted. Two months later the case was referred to Dr. Strobell for operation by the chemic method. The tissues lying within the circumscribed area, down to, but not involving, the periosteum of the ribs, together with an enlarged node, were removed by the chemic method and skin grafts placed on the granulating surface. Every graft took and the skin was now normal in color, quite freely movable, and possessed of normal glandular secretions. The operation was done in November, 1912, and at this reading the patient was in fine condition.

**Resection of the Esophagus for Carcinoma; Recovery.**—Dr. Franz J. A. Torek reported a case of resection of the middle portion of the esophagus for carcinoma, the first case that had ever been successfully operated. The operation was performed by him on March 14, 1913. The patient was sixty-seven years old. The tumor was just below the arch of the aorta. His incision was carried through the whole length of the seventh intercostal space from the posterior end of which it was continued upward, cutting through the seventh, sixth and fourth ribs at their angles; this method was simpler and gave a better exposure than any of the other methods of access To reach the part behind the arch of the aorta, a number of its thoracic branches were divided and the aorta was lifted forward. To do away with the danger of leakage from the upper stump of the esophagus, which had been the cause of many deaths, he dissected the

whole esophagus free and brought it out through an incision at the anterior border of the left sternocleidomastoid muscle. The patient made a satisfactory recovery. Dr. Torek called attention to the fact that success depended largely upon early diagnosis.

## NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

*Stated Meeting, Held March 18, 1913.*

DR. LINSLY R. WILLIAMS IN THE CHAIR.

**A Case of Crossed Paralysis and Right Hemiplegia with Aphasia Occurring Five Days Post-Partum.**—Dr. HENRY W. BERG reported this case which occurred in a woman thirty-three years of age whose family history was negative. She had been married five years and had three children. The first delivery, three years ago, was instrumental; the second was difficult; and the third, six days previous to the onset of her symptoms here related, was complicated by an adherent placenta which was extracted manually. She had a headache three days before and weakness of the right upper extremity. Inability to talk or understand speech developed on November 7, six days after the labor. Physical examination showed a right hemiplegia; abdominal reflexes were not obtained and there was flaccid paralysis of the right upper and right lower extremities. There was no Babinski sign present on the right side. She did not respond to questions or appreciate what was said. She had a lactating breast. On November 8 the right lower extremity was spastic, the knee jerks very lively, and the patient more apathetic and stuporous. In the evening the breathing was of the Cheyne-Stokes type and the right eye was turned outward and downward. There was right facial weakness, ankle clonus on the right side and Babinski's sign on both sides. The Wassermann test, blood culture, and cerebrospinal fluid were all negative. On November 9, Dr. Brettauer thought the condition was one of sepsis. On November 11, Dr. Sachs thought she had an infectious thrombus involving the pial veins, chiefly with exudate. On November 14, the general condition of the patient was better; she responded more readily when asked to hold up her hand, but had scarcely any power in the right hand or leg. There was complete recovery of the right eye muscle. There was left ptosis and internal strabismus and the pupil was dilated. On November 25, Dr. Friedenberg diagnosed a double optic neuritis. On December 6, the hemiplegia and reflexes were unchanged and the ptosis was clearing, but the patient was still having involuntary discharges. On December 30, the patient was up and in a chair but complained of painful contraction of the right upper extremity. There were right hemiplegia, knee jerks, right clonus, Babinski and Oppenheim signs. There was no longer any ocular palsy but the patient was still aphasic. By January 30, the general condition and most of the symptoms had improved though there were still marked right ankle clonus and Babinski. The urine was practically negative. The patient continued to improve and by March 14 could utter a few words. The sensory aphasia was slightly improved and she was slowly recovering the power to use her limbs. Of special interest was the fact that there was no cardiac lesion. Cardiac lesions or advanced cardiac diseases were not infrequently accompanied with hemiplegias during confinements; it was the excitement either before or after that caused in many cases of mitral disease an embolic deposit in the capsule with typical right or left hemiplegia. In the case reported the blood pressure was between 115 and 130. The question arose, what was the pathological cause in this case? Was there a thrombus of the veins of the pia with a deposit around the veins? Was there a thrombus of the large veins? Was there an embolus of the left side of the brain? Or was there a metastatic infarct complicating general sepsis? All these points had been thought of. Metastatic infarcts were not rare in such cases, and they came from the uterine sinus. An embolus in the pulmonary circulation was not rare and was due to an embolic deposit in the arteries or veins. In considering a thrombus of one of the veins one should consider the general circulation and the fact that in about 15 per cent. of the cases there was present a patent foramen ovale; therefore, an embolus would pass from the right or pulmonic side to the left or systemic side and so one could account for the resulting hemiplegia. Dr. Berg said he had seen cases of embolism in which four at least showed an embolus originating from a thrombus in the veins. On the seventh or eighth day Dr. Meyer discovered in this case a small nodule on the inner side of the leg; of course it was possible that this was present before it reached a size which would enable them to palpate it. From this there might have been thrown off an embolus which was carried in the circulation and deposited in the brain. It was also possible that Dr. Sachs's diagnosis was correct, a thrombus of the left side of the brain causing the symptoms. As to the location of the lesion in the left half of the brain, the symptoms indicated a crossed paralysis involving left ptosis and right hemiplegia with sensory and motor aphasia. There were both word blindness and word deafness; therefore, the trouble must have been located in the left cerebral hemisphere, to the inner side of the crux cerebri at or above the point where the third nerve left the hemisphere and would have to involve the motor tract fibers and the point of junction of the associated paths from the temporal and occipital lobe with the fibers from the third frontal convolution and island of Reil to account for the complete motor and sensor aphasia.

**A Case of Extreme Cardiac Hypertrophy.**—Dr. ALFRED MEYER presented this case. The patient was a woman, twenty-two years of age, an embroiderer. A point of special interest was that when twelve years of age, ten years ago, she was admitted to the old Mt. Sinai Hospital because of cardiac disease. She had measles at the age of one year, scarlet fever at the age of six, general edema lasting five months at the age of ten. On admission in October, 1903, she had an endocarditis. This patient had a mitral stenosis and insufficiency, and aortic stenosis and insufficiency, with edema of the eyelids and legs. The submaxillary, the post-cervical, and axillary glands were enlarged as were also those in the groin. The liver was much enlarged. She had cardiac palpitation, precordial distress, daily pains in the left shoulder, and slight dyspnea. There was no cough or expectoration. She had no appetite and was nauseated at times. There was no vomiting, no edema of the legs, no headache, or other symptoms. A second point of special interest was the excessive size of the heart. In the second interspace it extended two fingrs to the left of the sternum; the left border was two fingers breadth beyond the nipple line; the right border was one and one-half fingers outside the right border of sternum; the apex was seen and felt in the sixth space one and one-half fingers outside the nipple line. There was a double thrill at the apex, a double murmur at the apex, a double murmur at the base with systolic nodding of the head. A third point of special interest pertained to the diagnosis, comparison of the old and the newer methods, that was, the old method by percussion and the modern ones by fluoroscopy and skiagraphy. This was about the largest area of dullness due to mitral hypertrophy Dr. Meyer had ever encountered. The heart was enormously enlarged and especially on the right where it was increased beyond the right nipple. This case showed how easily compensation occurred; there was only a suggestion of dyspnea, practically no edema, and only a slight hepatic enlargement. Dr. Meyer called attention to the fact that the patient had scarlet fever when six years old and also a dropsy which lasted four months, and whether at this time there was an endocarditis or not, no one could say. There were fully developed lesions of both valves.

**Three Cases of Patent Ductus Arteriosus.**—Dr. MORRIS MANGES reported these cases.

CASE I.—This patient was thirty-five years of age and both her family and personal history were negative until four months before admission to Mount Sinai Hospital, when she noticed a progressive enlargement of the abdomen. She had no pain and complained of no other symptoms except that her urine was very scanty. A physical examination showed redness of the skin above and to the left and below and to the right of the umbilicus. At these situations the skin was hard, brawny, and infiltrated. This condition also obtained immediately around the umbilicus. Behind the left ear there was a cystic mass the size of a lemon over which the skin was adherent. There were hard shot-like glands above the clavicle, in both axillæ, and in both groins. The lungs gave evidence of fluid at both bases. The right border of the heart was six cm. from the median line in the second and third spaces. The left border was nine cm. to the left of the median line. The apex was in the fourth space in the midclavicular line. There was a short blowing systolic murmur at the apex which was transmitted a short distance to the left and also upward. In the second space it merged into a prolonged rumbling diastolic murmur. Both systolic and diastolic blowing murmurs were heard over the aortic area. In the first and second left interspace there was a prolonged systolic thrill. The veins of the abdomen were distended and there was a hard mass to the left of the umbilicus adherent to the skin and subcutaneous tissue. This mass was three inches in diameter

but there were no intra-abdominal masses palpable. There was edema of the legs. The cervix was adherent posteriorly. There was an irregular hard mass surrounding the rectum chiefly in front, causing an almost complete stenosis. There were cauliflower projections in the mass but no bleeding. An abdominal paracentesis was done and about 10,500 c.c. of fluid removed. The section of a nodule of abdominal wall was removed the pathological examination of which showed colloid carcinoma. An orthodiagram taken about a month later showed the heart pushed up by the diaphragm, pulmonary conus very large, projecting forward and pulsating more than any other structures visible. The left ventricle was overacting and the aorta pulsating excessively. This picture corresponded with that seen in open ductus Botalli. An analysis of the chest fluid showed lymphocytes 76 per cent. and polymorphonuclears 24 per cent. The Wassermann reaction was negative. This patient was readmitted to the hospital three months later complaining of extreme weakness, dyspnea, and swelling of the abdomen. There was marked cachexia. The umbilical mass was larger than at the time of the previous admission and the heart showed dullness in Gerhardt's space, where a systolic thrill could be heard. At the apex there was a systolic murmur transmitted to the left. In the second left intercostal space there was a continuous roaring murmur, transmitted to the left and upward. The patient died suddenly on the day of admission and autopsy revealed carcinoma of the stomach, pylorus, ovaries, ascending, descending, and transverse colon, and rectum. There was a patent ductus arteriosus with a valve-like arrangement leading into the aorta. There was a conical opening into the ductus arteriosus which measured one cm. in diameter at its mouth and halfway surrounding the orifice of which was a shallow atheromatous plaque about three by ten mm. in dimensions. This opening led into the ductus downward and forward, and a probe could be readily inserted which emerged through the irregular orifice of the thrombus which surrounded the opening into the pulmonary artery. Beyond this the thoracic aorta was normal, showing a few irregular fatty streaks in the intima and measuring 42 mm. in circumference.

Case II.—This patient was admitted to Mount Sinai Hospital on June 26 and discharged July 18, 1912. She was fifty years of age and had had cardiac trouble for two years. Six weeks before her admission she suffered from a typical attack of sciatica, and three weeks after this developed headache, nausea, precordial pain, and cardiac palpitation. She had slight edema of the feet and scanty urine. The upper border of the heart was in the third interspace, the right border at the right border of the sternum, and the left border one finger outside the midclavicular line. The apex was in the fifth space in the midclavicular line. At the apex there was a faint systolic thrill and soft systolic murmur which was transmitted to the right and left. Over the second left interspace about two fingers to the left of the left sternal border was seen a marked systolic pulsation which could be followed to the midclavicular line of the left side. Over this area there was a rough systolic thrill transmitted upward to the first space and downward to the third and fourth spaces there was a rough systolic murmur. The heart condition remained the same while the patient was in the hospital. The orthodiagram report showed the heart approximately normal in size. The position was slightly to the left of normal. The pulmonary artery was very large and pulsated excessively.

Case III.—This patient was a woman, thirty years of age, whose family and personal history were negative. Her present illness began five months before her admission to the hospital when she noticed that she was becoming hoarse. Three weeks before admission she noticed extreme nervousness, cardiac palpation, and bulging of the eyes. These symptoms had increased. A diagnosis was made of exophthalmic goiter, patent ductus arteriosus, and chronic endocarditis. The right border of the heart was two fingers to the right of the sternum, the left border in the midclavicular line, and the apex beat in the fourth space. The action was very rapid and regular. There was a loud blowing systolic murmur at the apex transmitted to the left and heard all over the precordium and in the vessels of the neck. There was a loud rumbling systolic thrill present over the apex and over the pulmonic area. The object of this presentation was not to discuss the diagnosis but to show the use of orthodiagraphy, and Dr. Manges referred to Goodman's report, covering a period from 1847 to 1910, in which there were 34 cases with autopsy and 37 without autopsy. If the *x*-ray was used more frequently he believed that more of these cases would be diagnosed. Many diagnoses could now be made by the use of the orthodiagraph that could not be made in former years. In Dr. Meyer's wards at the Mount Sinai Hospital, one man had made a diagnosis of patent ductus arteriosus in five cases (four in children and one in an adult thirty years old), and another man had made such a diagnosis in three adults, 30, 35, and 50 years of age respectively. These diagnoses were made on physical findings and confirmed by the orthodiagrams. The reason for overlooking congenital cases was that most practitioners associated congenital lesions with cyanosis and clubbed fingers. Sometimes it was forgotten that longevity was not incompatible with congenital lesions; when these were absent, the lesions were often overlooked. Furthermore there were discrepancies among writers as to the exact description of the physical signs and the variations of the hypertrophies of the ventricles, the confusing interrelation of various lesions, etc. In the present lesion, the diagnosis ought to be readily made unless there were unusual complications. Dr. Manges' own belief was that some of these cases were mistaken for mitral lesions. The diagnosis was made on (1) murmur and thrill with transmission to interscapular region; (2) accentuation of second pulmonic sound; (3) Gerhardt's zone; this was not constant; (4) absence of cyanosis and hypertrophies unless complications existed; (5) *x*-ray plates, but these were not so good for diagnostic purposes in these cases; (6) orthodiagraph. In differential diagnosis it was noted that in open septum there was no cyanosis; there was a loud rumbling systolic murmur and thrill in the upper precordium over the sternum, not transmitted into the vessels; there was no accentuated second pulmonic sound and no hypertrophy. In aortic stenosis there was no accentuated second sound and the murmur was heard to the right. In mitral disease the mitral murmur was heard loudest over the mitral valves, and not at the apex. Where there were complications, as so frequently occurred, the diagnosis might be very difficult, as a study of some of the reported cases readily showed, for the associated lesions might cause great confusion. Hence the great value of orthodiagraphy when the diagnosis was made by sight and by the interpretation of the accompanying murmurs. The number of cases in which the diagnosis had been confirmed by autopsy was sufficiently large to warrant their trusting the interpretation of the orthodiagraphic picture. Fortunately they were able to obtain an autopsy in the one case that died.

**On the Relation of $O_2$ to Bone Marrow Function.**—Dr. Nathan E. Brill read this paper. He stated that the erythrocytes or red blood discs of mammals ought not to be regarded morphologically as cells since they lacked a nucleus, centosome, and internal signs of cell architecture. Though their stroma contained chemically the nucleoproteids and lipoids, event in about the same relative proportion that was characteristic of protoplasm, they represented a protoplasm which had lost the functions of cellular protoplasm, such as motility, etc., and had become changed into lipoid shells whose chief function was to contain hemoglobin in solution. On the other hand erythroblasts, whether megalo- or normoblasts as they occurred in the bone marrow showed the properties of cells; they contained a nucleus, underwent mitotic division, etc., and were converted finally into erythrocytes, losing their original characteristics and probably some of their early functions. It appeared, therefore, that the red blood discs of mammals were chiefly hemoglobin containers and as such were the most important factor in binding and carrying the most essential of all chemical elements of the body, $O_2$. Without oxygen the activities of every known tissue cell, including the erythrocytes themselves, would fail. The essential feature of the oxygen carried to the tissues for purposes of assimilation and by which they derived the energy for their activities was that it should be carried in its molecular form. The mechanism which supplied the oxygen carriers and maintained an equilibrium between their loss and their supply was supposed to reside in the bone marrow. The author had been teaching for the past six years that the bone marrow was so attuned to the amount of oxygen that was carried to it by the erythrocytes that it immediately responded by throwing out new cells when sufficient oxygen was not supplied. In other words oxygen acted as the hormone which called for the erythroblastic activity of the bone marrow. An analogous process was supplied by some other organs, notably the liver. Just as the needs of the muscles for carbohydrate (sugar) to supply the pabulum for their energy must be announced to the liver, so the needs of all the tissues for oxygen must be announced to the bone marrow through the oxygen carriers, the red blood cells themselves. The red blood cells were the active agents which demanded from the marrow an increase in their number whenever they were insufficient to distribute the necessary amount of oxygen to the other members of the cell communities. The bone marrow re-

sponded to this call when the carriers themselves were deficient in hemoglobin which was considered to be the substance which bound the oxygen or, to be more accurate, the iron containing radicle, hemochromogen, combined with protein compounds forming hemoglobin was responsible for the power of the hemoglobin radicle to form compounds with molecular oxygen. This compound was very unstable. Hence, if for any reason the oxygen carriers were diminished, as by loss of blood, or by molecular, chemical, or other changes in the hemoglobin which would interfere with its power to bind oxygen, the bone marrow would respond by immediately increased activity. The activity followed physical laws and naturally depended on the intensity of the stimulus. If the demand for oxygen was immediate and urgent, the bone marrow threw out embryonic forms in the shape of megaloblasts and normoblasts; if the need was not so urgent, the marrow completed its development of the red cell and supplied the blood with fully formed erythrocytes. The former retained the characteristics of true cells; the latter, in the process of development lost them. The former, cell for cell, contained a much greater amount of hemoglobin and hence, inferentially, were of greater oxygen carrying capacity. It seemed that such erythroblastic activities could be called forth by other local pathological conditions such as direct irritation of the bone marrow, as, for instance, by tumors of the bones, even by certain general causes such as toxines, hemolytic agents in the blood, infectious disease agents, bacteria, and by certain general causes like those in leukemia. Experimentally it had been shown by F. Müller that if the artery to a marrow-containing bone was ligated, the blood returned by the vein from such a bone contained an increase in the number of red cells among which were found a large proportion of nucleated forms. In other words an immediate response was made by the bone marrow to the urgent call for oxygen. It was possible that other unsatisfied nutritional demands of the bone marrow might have been added stimuli to call forth the erythroblastic activity in this experiment. This entire theory was borne out clinically: 1. Where oxygen was diminished by reason of diminished pressure due to high altitude. 2. Where oxygen was displaced by a gas having greater combining power with hemoglobin, as for instance, carbon monoxide poisoning. 3. Where carbon dioxide existed in excess as in pulmonary and cardiac conditions, both congenital and acquired, or by the use of the Kuhn mask. 4. Where large quantities of blood were lost, as in hemorrhages acute and chronic. 5. Hemolytic blood conditions, as Banti's disease, pernicious anemia, chronic splenomegalic acholuric jaundice. 6. In infectious diseases, typhus particularly. 7. In leukemias. 8. Where hemoglobin was molecularly changed as in chlorosis.

In all of these disturbances and disease conditions clinical investigation had shown erythroblastic activity, either by a polycythemia or by the presence of nucleated red blood cells or by both.

The author stated that he was engaged, as he had been for some months, in investigating with Dr. S. Bookman of the chemical laboratory of the Pathological Department of Mount Sinai Hospital the total oxygen capacity of normal blood and of blood obtained from patients with mostly all of the disease conditions just enumerated. Experimental work, however, had shown to them a large percentage error in oxygen determination due to what would appear to be defects in the Barcroft-Haldane instrument, in the difficulty in maintaining an absolute temperature equality in the experiment, and in barometric pressures though the differential instrument was used. Therefore the entire communication should be considered as merely a preliminary one.

Dr. Arthur Bookman said that they had been endeavoring to determine the amount of available oxygen in the blood, as well as the carbon dioxide $CO_2$ therein contained, by means of the differential apparatus of Dr. Barcroft. Unfortunately their results with pathological blood from several cases of anemia varied between rather wide limits showing differences of 30 to 40 per cent., the same blood showing wide variations. The determination of the oxygen liberated from chemically pure solution of hydrogen peroxide showed differences of plus 20 per cent. In four different determinations, however, the average of 5.4, compared with the theoretical quantity of 5.52, showed a rather close agreement, but the limits of 4.6 and 6.3 showing, as above stated, a variable error of plus 20 per cent. made it impossible to apply this apparatus for these determinations. Further investigations, however, might be reported at a later date should they be successful in eliminating these divergent results. The cause for these wide discrepancies lay no doubt in the fact that gases expanded 1/273 of their volume for the rise of each degree centigrade, and as the apparatus had a volume of about 25 c.c. on each side of the manometer, and the manometer tube registered in c.c. differences of only fractions of a degree in temperature, would easily produce these wide divergencies. It might be possible that by using certain controls that this error might be eliminated which he hoped to be able to perform at some future date.

**Acquired Splenomegalic Hemolytic Icterus.**—Dr. Nathan E. Brill reported this case. He said the object of reporting it was to get a case of this very rare disease group on record because he knew of no other reported case outside of those of Dr. L. E. Conner of the New York Hospital. The case reported was distinctly one of the acquired form of this disease. No other member of her family had ever had jaundice. Up to the age of thirteen this girl, now twenty years old, was perfectly well. At thirteen she had an attack of scarlet fever which left her very anemic. A few months thereafter her physician noted that her spleen had enlarged. The anemia persisted and two and a half years ago it was noticed that her skin and sclera became yellow. This icteric hue varied in intensity from a light to a deeper yellow. At times it disappeared. In the past two and a half years she had noted five distinct attacks of deep discoloration of her eyes and skin. Following the beginning of her icteric discoloration she developed on each leg a small round ulcer which at intervals impaired the function of her ankle joints. It was owing to the discoloration of her skin and the unhealed ulcers on her legs that she sought admission to Dr. Brill's service at Mount Sinai Hospital, Oct. 28, 1912.

On admission examination disclosed the following: Female, small stature, brunette, pale, yellowish tinge to conjunctivæ, with skin of a pale yellow hue (tint something like the yellow of pernicious anemia). The body was well nourished. The pupils were equal, regular, central, and reached to light and accommodation. There were no palsies, no patechiæ, and no ecchymoses. The examination of the nose, throat, ears, and mastoids was negative. There was no thyroid enlargement. The lips and buccal mucosa were pale, the teeth good, the tongue moist, the tonsils not enlarged. The submaxillary lymph nodes were palpable, otherwise there were no lymph-node enlargements. The chest was well formed, expansion was good, and there was slight tenderness over sternum. The lungs were negative. The right border of the heart was at midsternum, the upper border at third rib; left border in mid-clavicular line; the apex in fifth space, three and one-half inches from midsternal line. The sounds were clear. There was a systolic murmur over the pulmonary valve. The pulse was regular, with good force and volume. The examination of the abdomen showed the fat preserved, lax, tympanitic, and no tenderness. The liver was enlarged, with upper border at fourth interspace and lower border palpable 3 c.m. below the margin of the ribs in the mid-clavicular line. The surface was smooth, with firm, rounded edge. The spleen was enlarged; the upper border reaching to seventh interspace, and the lower border palpable 3 c.m. below the left costal margin. The surface was smooth and the edge was firm and rounded. There was no tenderness over the liver or the spleen. The extremities showed no tibial tenderness. In the right leg there was some periarticular thickening around the ankle joint with some limitation of motion; there was slight inward rotation of the foot; it was also slightly extended. There was an oval ulcer 2c.m. in diameter posterior to the inner malleolus covered by a scab, very tender and surrounded by an area of indurated, inflamed tissue. The foot of the left leg was extended and everted with similar periarticular thickening; it was also the seat of an ulcer of same size, in front and above external malleolus, covered by unhealthy granulations and surrounded by thickened area of discolored and inflamed skin; the ulcer was adherent to the bone.

*Urine*—Sp. Gr. 1022, acid, no albumin, no casts, no sugar, *no bile*.

*Blood*—Red blood cells, 4,100,000; hgb., 74; color index, 0.9+; normoblasts, 3 to 100 white blood cells; megaloblasts, occasional; polychromasia, definite and general; anisocytosis, well marked; some granular degeneration; white blood cells; total, 15,000.

The percentage count was as follows: Polynuclear, 73½ per cent.; small lymphocytes, 20 per cent.; large lymphocytes, 5 per cent.; basophiles, 1 per cent.; eosinophiles, ½ per cent; white cell count, 200. At no time during the three months of the patient's stay in the hospital did the urine contain bile pigments. The blood serum, while showing a yellowish tint, gave no reaction for bile. Numerous tests for bile in the blood and urine at frequent intervals were made with negative results. The feces always contained bile.

The blood examinations were as follows:

Nov. 1, 1912—R. B. C., 3,800,000; Hgb., 70; color index, 0.9 +.

Nov. 12, 1912—R. B. C., 4,400,000; Hgb., 74; color index, 0.85.

*Smears*—Stain with *vital staining* method showed perfect peripheral granules in about one out of every twelve red blood cells.

*Corpuscular fragility:*

| Saline per cent., 5 drops blood to 5 c.c | Taking |
|---|---|
| 0.3 | Complete. |
| 0.325 | Complete. |
| 0.35 | Complete. |
| 0.375 | Complete. |
| 0.4 | Complete. |
| 0.425 | Complete. |
| 0.45 | Not entirely complete. |
| 0.7 | Begins. |
| 0.75 | Doubtful. |
| 0.8 | Absent. |
| 0.9 | Absent. |

The blood thus showed a definitely increased fragility.

Nov. 21, 1912—R. B. C., 4,100,000; W. B. C., 10,750; anisocytosis; index, 0.6 +; Poly., 69 per cent.; poikilocytosis; S. Lmph, 27 per cent.; polychromasia; L. Lymph., 1 per cent.

Nov. 29, 1912—R. B. C., 3,200,000; Hgb., 80; color index, 1.+. (Few normoblasts). W. B. C., 8,800: Poly, 73 per cent.; lymphocytes, 27 per cent.

Dec. 5—R. B. C., 2,970,000; color index, 0.9; W. B. C., 6,100; poly., 67 per cent.; lymphocytes, 30 per cent.; basophiles, 3 per cent.

Dec. 12, 1912—R. B. C., 3,800,000. (Few normoblasts.) No megaloblasts; definite poikilocytosis, anisocytosis, microcytes, and macrocytes, granular degeneration and polychromasia.

In about one month the leg ulcers healed under the application of scarlet red.

Dec. 13, 1912.—The patient still showed moderate pallor with slight icteric tinge; there was a slight icteric hue of the sclera.

The physical signs were as before. There was no diminution or increase in size of liver or in the size of the spleen.

Dec. 17, 1912—R. B. C., 4,300,000; Hgb., 83 per cent. Normoblasts and macrocytes numerous; W. B. C., 6,800; Poly., 67 per cent.; S. Lymph., 30 per cent.; Basophiles, 2 per cent.; Eosinophiles, 1 per cent.

Dec. 25, 1912—Blood still showed normoblasts, macrocytes with marked vital staining cells, increased corpuscular fragility; hemolysis starting at .75 and ending at .45; granular degeneration, polychromasia, poikilocytosis and anisocytosis definitely marked.

The following examinations were completed in the laboratory of the pathological department.

Dec. 1, 1912—Duodenal contents contained abundant bile secretion, thick and viscid. The pancreatic ferments gave the following reaction: Amylasa, strong; lipasa, moderately strong; trypsin, strong. (Dr. Crohn).

Three blood examinations (Wassermann) were all negative. (Dr. Kaliski).

Urine—Total N = 2.831 grms; ammonia N = 0.271 grms., 9 per cent.; nucleo-protein, small amount. (Dr. S. Bookman).

Blood—Negative for bile. (Dr. B. Crohn).

Dec. 7, 1912—Iron in 24 hour urine; total, 1.2 m. grms.; urobilin strongly present.

Gastric contents showed ferments strongly present, both pepsin and renin.

The increased amount of excreted iron, the urobilin in the urine, the hepato and splenomegaly showed this to be an example of a hemolytic disease. It is very possible that the icterus, if such it might be called, was due to some other products of catabolized hemoglobin such as urobilin. It was certainly not due in this case to bile pigment as such, for no bile pigments existed in the blood or urine, and bile was being continually excreted in the feces. The distinctive signs of erythroblastic activity, such as nucleated forms, vital staining red cells, and the diminished osmotic resistance (fragility) of the red blood cells relegated this case to the group under discussion.

### Philadelphia Neurological Society

At a stated meeting held March 28 Dr. Alfred Gordon presented "A Case of Neurofibromatosis." The patient was a man, 27 or 28 years old, who had noticed tumors of varying size appearing successively in many parts of the body. They were situated in the course of nerve-trunks; some of them were painful at times and many of them the seat of tenderness. There were no other sensory phenomena, while the motor functions were undisturbed and the reflexes preserved. Varied treatment, including radium emanations, had been employed, but without appreciable effect. The case was extraordinary by reason of the large number and wide distribution of the growths.

Dr. Edward A. Shumway read by invitation a communication entitled "Bilateral External Rectus Paralysis Due to Traumatism." The condition was observed in a wagon-driver who was thrown to the ground from his seat, injuring the left side of his head. There was a bloody discharge from one ear, with impairment of hearing on that side, and double vision, with loss of power in the external rectus muscle of each eye. The condition was attributed to a fracture at the base of the skull. Improvement took place under treatment.

Dr. H. Maxwell Langdon read a paper entitled "Bilateral Partial Paralysis of the Third and Sixth Nerves with Optic Atrophy." The patient was a man about 48 years of age, who in addition to loss of vision and impairment of motility on the part of the muscles controlled by the third and sixth nerves on each side, presented loss of knee-jerk on one side with diminution on the other side, polyuria and diminished pupillary reaction to light. The blood yielded a positive Wassermann reaction.

Dr. John H. W. Rhein reported "A Case of Bilateral Facial Paralysis of Peripheral Origin." The patient was a girl about 18 years old who worked at an open window and developed paralysis of the external rectus muscle of one eye, followed after an interval of some weeks by paralysis of the muscles on one side of the face and a few days later by paralysis of the muscles on the opposite side of the face, together with some impairment of the sense of taste on the anterior portion of the tongue. The facial muscles exhibited reactions of degeneration. The blood yielded a negative Wassermann response. Marked improvement ensued upon treatment.

Dr. William G. Spiller presented "A Case of Dystonia Musculorum Deformans." The patient was a man who exhibited a peculiar gait comparable to that of a monkey, and, while quiet at rest, developed incoordinate movements on attempted action. There was some deformity of the pelvis and a certain degree of spasticity. The knee-jerks could not be elicited. Dr. Spiller presented also "Three Cases with Tremor Resembling that of Multiple Sclerosis." All of the patients, of different age, were alcoholics, and each presented coarse, incoordinate movements on attempts at motion, but there was no nystagmus and no alteration in reflexes. Dr. Spiller pointed out the rarity of disseminated sclerosis in the United States as compared with its relatively greater frequency on the continent of Europe. In fact, cases that during life have presented symptoms of disseminated sclerosis have on autopsy proved to be entirely free from the lesions of that disorder.

Dr. James Hendrie Lloyd presented "A Case with Marked Ataxia of the Arms." The patient was a blacksmith, without history or other evidence of syphilis, who presented ataxic movements of the upper extremities, with astereognosis and hypesthesia of the fingers, with exaggerated knee-jerks and slight nystagmus, but without disturbance of speech or derangement of micturition.

Dr. S. D. W. Ludlum reported "A Case of Injury of the Internal Popliteal Nerve Associated with Double Crutch-palsy."

## State Medical Licensing Boards.

### STATE BOARD EXAMINATION QUESTIONS.

Medical Examiners of New Jersey.

*October*, 1912.

ANATOMY.

1. Describe the articulations of the vertebral column.
2. Parotid gland: Give blood and nerve supply; what vessels pass through it?
3. Describe the facial artery; give its relations, name its branches.
4. Describe the third cranial nerve, what would be the result of cutting that nerve?
5. Locate and describe: (*a*) Villi, (*b*) Crypts of Lieberkühn, (*c*) Brunner's glands, (*d*) Peyer's glands.
6. How could you define the course of the femoral artery?
7. Name and describe the two largest ganglia in the body.
8. Describe the nasal fossæ; give blood and nerve supply.
9. Describe the superficial inguinal glands. What lymphatic vessels do they receive?

10. In fracture of the middle of the clavicle, what muscles cause displacement of the fragments?

PHYSIOLOGY.

1. Are the auriculoventricular valves ever open at the same time? Explain.
2. Why is blood pressure in the aorta higher than in the small arteries?
3. Can there be a venous pulse? Explain.
4. Name five factors that influence the lymph circulation.
5. What are the sources of the white and red blood cells, and what are their sepcial functions?
6. Name the properties of a living cell.
7. What is the essential cause of "old sight?"
8. Can the pupil of a blind eye react to light?
9. Compare the path of motor nerve impulse to a voluntary muscle, with that to involuntary muscle.
10. What is the result of injury to the semicircular canals?
11. Name, in order of importance, the heat-producing organs.
12. Name, in order of importance, the organs which dissipate body heat.
13. What nerve centers regulate body temperature?
14. Give composition of protein, starch, carbohydrates, sugar, and fat.
15. What digestive disturbance follows removal of the pancreas?

CHEMISTRY.

1. Of how many elements is matter composed?
2. Give the definition of an element; a compound; a mixture.
3. What chemical tests are most important in the analysis of urine?
4. Give composition of corrosive sublimate, and antidote for poisoning by it.
5. Name the three most important alkaloids derived from opium; give the dose of each.
6. Name some of the compounds of iron.
7. How is arsenic obtained in its metallic state? What are its physical and chemical properties?
8. How would you distinguish carbolic acid from creosote?
9. What is the chemical difference between carbo animalis, U. S. P., and carbo ligni, U. S. P.?
10. Give the best antidote for arsenic poisoning, and how may it be quickly prepared?

MATERIA MEDICA AND THERAPEUTICS.

1. Name active principles, preparations, and doses of nux vomica, antidote for poisoning.
2. Give the official iodine preparations, medicinal properties, dose, and methods of employment.
3. Name specific treatment for diphtheria and state briefly how remedy is obtained, dose and how it is administered.
4. Name the official bromides. Doses of each.
5. Name three drugs that render the urine alkaline; indications, doses and methods of administration.
6. Give the physiological action of ergot and mention its therapeutic uses, preparations, and dosage.
7. What are the most important silver preparations? Indicate therapeutic uses, dose, antidote.
8. In what way does strophanthus differ in physiological action from digitalis? What is dose of each?
9. Name preparations of ammonia, principal indications for its use. Dose.
10. When and under what conditions would you use veratrum viride? Name preparation and dose.

HISTOLOGY.

1. Draw a cross section of the spinal cord and describe your findings.
2. Describe the cerebral cortex.
3. Describe the pineal gland.

## ANSWERS.

ANATOMY.

1. *The articulations of the vertebral column* consist of joints between the bodies of the vertebræ and joints between the neural arches by means of the articular processes. The former are amphiarthroses, the latter diarthroses. The *bodies* are united by the anterior common ligament, the posterior common ligament, and the intervertebral substance. The laminæ are connected by the ligamenta subflava. The articular processes are surrounded by the capsular ligaments. The ligaments of the spinous processes are: The interspinous ligaments, the supraspinous ligament, and the ligamentum nuchæ. The intertransverse ligaments extend between the transverse processes.

2. The *blood supply of the parotid gland* is derived from the branches of the external carotid which pass in or near it: The posterior auricular, internal maxillary, superficial temporal, and transverse facial. The *nerve supply of the parotid gland* is from the sympathetic plexus on the external carotid artery, and the facial, auriculotemporal and great auricular nerves. *Vessels which pass through the parotid glond* are: External carotid, posterior auricular, internal maxillary, superficial temporal, and transverse facial arteries; internal maxillary, temporal, and temporomaxillary veins.

3. *The facial artery* is a branch of the external carotid; it arises near the angle of the lower jaw, passes forward and upward beneath the digastric and stylohyoid muscles. From the base of the jaw it turns up over the face, running anterior to the masseter muscle; it then passes across the cheek to the angle of the mouth, then along the side of the nose to terminate in the angular artery, at the inner canthus of the eye. *Relations:* In the neck it is covered by the skin, platysma, and fascia; next, it is crossed by the posterior belly of the digastric and the stylohyoid; it then passes through the submaxillary gland. In its course on the face it rests on the lower jaw, the buccinator, the levator anguli oris, and the levator labii superioris; it is covered by the skin, platysma, and zygomatic muscles, and is crossed by branches of the facial nerve. *Branches:* Ascending palatine, tonsillar, submaxillary, submental, inferior labial, inferior coronary, superior coronary, lateral nasal, angular, and muscular.

4. The *third cranial nerve* (motor oculi) arises from the inner side of the crus cerebri, in front of the pons, and from the floor of the aqueduct of Sylvius. It enters the cavernous sinus and then passes forward to enter the orbit through the sphenoidal fissure. While in the sphenoidal fissure it divides into two branches. It is the motor nerve for the muscles of the eyeball, and is distributed to all of these muscles except two. It supplies the superior rectus, levator palpebræ superioris, internal rectus, inferior rectus, and inferior oblique muscles. *If the nerve is cut:* The pupil will be dilated and there will be no response to either light or accommodation; ptosis will follow; diplopia will result; external squint will be noticed, and the eyeball will protrude and remain immovable.

5. *Villi* are found throughout the small intestine. They are minute processes projecting from the mucous membrane of the small intestine and are situated on the valvulæ conniventes and also between them. They consist of a lacteal, blood vessels, epithelium, basement membrane, and lymphoid tissues. *Crypts of Lieberkuhn* are minute tubular depressions in the mucous membrane of the small intestine; they run perpendicularly to the surface and open at the base of the villi. They are found throughout the small intestine. *Brunner's glands* are found in the duodenum. They are in the submucous coat and pierce the mucous coat and occur most abundantly near the pylorus. *Peyer's glands* occur chiefly in the ileum; a few are found in the jejunum, and occasionally they may be found in the duodenum. They are patches of solitary follicles, varying in length from a half to four inches.

6. If the thigh is flexed and rotated outward, a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis, to the inner side of the internal condyle of the femur, will indicate the course of the femoral artery.

7. *The two largest ganglia in the body* are the two semilunar ganglia which are situated one on each side of the solar plexus. They are formed by the aggregation of smaller ganglia. They are situated in front of the crura of the diaphragm, near to the suprarenal glands, and take part in the formation of the solar plexus.

8. The *nasal fossæ* are two irregular cavities situated in the middle of the face. They open in front by the anterior nares, and behind into the nasopharynx by the posterior nares. They are separated by the septum, which is generally deviated to one side. The mucous membrane lining the nasal fossæ is called the Schneiderian membrane. Each fossa has a roof, a floor, an inner and an outer wall. From the outer wall there project into each fossa the superior and middle turbinated processes of the ethmoid bone, and the inferior turbinated bone; these bony processes divide each fossa into a superior, middle, and inferior meatus. The nasal fossæ communicate with the sphenoidal sinus, the anterior and posterior ethmoidal cells, the frontal sinus, and the antrum of Highmore.

*Blood supply:* anterior and posterior ethmoidal and sphenopalatine arteries. *Nerves:* Nasal branch of ophthalmic, anterior dental, Vidian, nasopalatine, and anterior palatine. The olfactory is the nerve of special sense of smell.

9. The *superficial inguinal glands* are from ten to twenty in number and are situated just below Poupart's ligament, immediately under the superficial fascia in Scarpa's triangle. They receive the lymphatics from the skin of the penis, scrotum, perineum, buttocks, and lower abdominal wall.

10. In *fracture of the middle of the clavicle:* The *outer fragment* is drawn *downward* by the weight of the limb, the pectorals, and latissimus dorsi; *inward* by the levator anguli scapulæ, trapezius, rhomboids, pectorals, and latissimus dorsi; and is rotated *forward* by the pectorals and serratus magnus.

PHYSIOLOGY.

1. Certainly, the auriculoventricular valves are open at the same time; this occurs during auricular systole and during the latter part of auricular diastole.

2. The blood pressure in the aorta is higher than that in the smaller arteries, because: (1) The resistance in the aorta is higher; and (2) the sectional area of the aorta is smaller than the sectional area of the smaller arteries combined.

3. *Venous pulse.* "Under usual conditions the pulse wave is lost before entering the capillary regions, but as a result of dilatation in the arteries of an organ the pulse may carry through and appear in the veins, in which it may be shown, for instance, by the rhythmical flow of blood from an opened vein. The term *venous pulse,* however, as generally used applies to an entirely different phenomenon—namely, to a pulse seen especially in the external jugular vein. When this vein is prominent or is made prominent by some compression a pulse may be seen and recorded which is synchronous with the heart beat. It is not a wave that has come through the capillary circulation in the head, since if the vein be completely blocked by the finger the wave disappears on the upper side. It is due to the heart beat, and is usually attributed to the auricular contraction. At each contraction of the auricle the venous flow is partially blocked; at each relaxation the flow is suddenly augmented. Under pathological conditions a marked venous pulse of a different origin may be seen in the jugular or may be felt over the liver (liver pulse). This wave is usually described in connection with an insufficiency of the auriculoventricular valves. Under such a condition it is evident that the contraction of the ventricles will be accompanied by a regurgitation toward the auricles and the production of a positive wave in the venæ cavæ and their branches."—(Howell's *Physiology.*)

4. *Five factors that influence the lymph circulation:* (1) The pressure of the blood in the bloodvessels; (2) thoracic aspiration; (3) contractions of the voluntary muscles; (4) contractions of the intestine; (5) the action of the valves in the lacteals and lymphatics.

5. *Source of white blood cells:* Lymph tissues, spleen and bone marrow. *Source of red blood cells:* Red bone marrow. *Function of red blood cells:* To supply the tissues with oxygen. *Function of the white blood cells:* To serve as a protection to the body from the incursions of pathogenic microorganisms; they take some part in the process of the coagulation of the blood; they aid in the absorption of fats and peptones; and they help to maintain the proper proteid content of the blood plasma.

6. *A living cell* has the properties of: Irritability, movement, ingestion, assimilation, excretion, growth, and reproduction.

7. The essential cause of old sight is diminished elasticity of the lens; diminution of the convexity of the cornea may also be a cause.

8. The pupil of a blind eye can react to light; for although the direct reflex is abolished, yet the consensual reflex remains.

9. To a *skeletal muscle* the motor nerve impulses start in the cortex cerebri, and pass through the corona radiata, internal capsule, crus, pons, medulla, crossed and direct pyramidal columns to the motor cells of the anterior horn of the spinal column, thence through the nerve root and motor nerve to the muscle. To *involuntary muscle:* The efferent fibers of the sympathetic nervous system arise in the intermediolateral column of gray cells. They pass out by the anterior root from the spinal cord. From here they go by a white ramus to a sympathetic ganglion. From the sympathetic ganglion they may pass in two directions: (1) they may form synapses about these cells and from these cells new axons may arise and pass outward in the visceral nerves or back through the gray ramus connected to the ganglion, into the spinal or somatic nerve to the bloodvessels as vasomotor nerves, or to sweatglands as secretory nerves, or to hairs as pilomotor nerves; (2) or they may pass through the ganglion on to one situated more toward the periphery, in which they form synapses and are continued onward by new axons.

10. *Injury to the semicircular canals* may cause: Nausea, vertigo, loss of sense of equilibrium, loss or impairment of muscular sense, unsteadiness in gait.

11. The *heat-producing organs* are: The muscles, secreting glands (chiefly the liver), digestive tract during digestion, and the brain.

12. *Heat is lost to the body,* by: The skin, through evaporation, radiation, and conduction; the lungs; and the excretions (urine and feces).

13. *The nerve centers which regulate body temperature* are: The thermotactic, thermogenetic, and thermolytic centers. The location of these centers is not known.

14. *Protein* is composed of carbon, hydrogen, oxygen, nitrogen, and sometimes sulphur, iron, phosphorus or some other element. The composition of *starch* is shown by its formula $(C_6H_{10}O_5)n$. *Corbohydrates* contain carbon, hydrogen, and oxygen, the two latter in the proportions to form water. *Sugar* (like starch) is a carbohydrate, and contains the same elements. *Fats* contain carbon, hydrogen and oxygen, but not in the same proportions as in carbohydrates.

15. There would be a decided diminution in the activity of the digestion of all kinds of foods—particularly of proteids and fats; there would be noticeable carbohydrate indigestion, and starch would be abundant in the stools.

CHEMISTRY.

1. There are about eighty elements.

2. An *element* is a kind of substance which we cannot, by any known means, split up into any two or more other kinds of substance.

A *compound* is a substance made up of two or more elements, chemically united, in definite proportions.

A *mixture* is the product obtained by uniting into a more or less homogeneous whole two or more substances, whether elements or compounds.

3. See below, PRACTICE OF MEDICINE. *Question* 10.

4. Corrosive sublimate has the formula $HgCl_2$, thus showing that each molecule contains one atom of mercury and two atoms of chlorine. The *antidote* is white of egg in moderate quantity, followed by an emetic.

5. Morphine, dose gr. 1/5; codeine, dose gr. ½; thebaine.

6. Ferric oxide, ferric hydroxide, ferrous sulphide, ferric chloride, ferrous sulphate; also the carbonate, citrate, hypophosphite and salicylate of iron.

7. Arsenic is obtained by heating a mixture of arsenic trioxide and charcoal, and then purifying the product by resublimation.

Arsenic is a gray solid, odorless and tasteless, a good conductor of electricity, it may be crystalline or amorphous, its vapor has the odor of garlic. It is insoluble in water; when heated in air it is converted into arsenic trioxide; in the presence of moisture it becomes tarnished.

8. Carbolic acid is soluble in glycerin; creosote is insoluble (or nearly so) in glycerin. With alcohol and ferric chloride, carbolic acid gives a dark brown or yellow color; creosote gives a green color.

9. *Carbo animalis* is charcoal prepared from bone; *carbo ligni* is charcoal prepared from soft wood.

10. The best antidote for arsenic is a freshly prepared solution of ferric hydroxide. The two following solutions should be kept in separate bottles, and when needed mixed and administered.

(1) ℞. Liquoris ferri tersulphatis ℥ij.
Aquæ destillatæ ℥vj.

(2) ℞. Magnesiæ ℥iij.
Aquæ destillatæ ℥iij.

MATERIA MEDICA AND THERAPEUTICS.

1. The *active principles* of nux vomica are strychnine, brucine, and igasuric acid.

*Preparations and doses:* Extractum nucis vomicæ, gr. ¼; fluidextractum nucis vomicæ, ♏jj; tinctura nucis vomicæ, ♏x; strychnine, gr. 1/64; strychninæ sulphas, gr. 1/64; strychninæ nitras, gr. 1/64.

*Treatment of strychnine poisoning:* The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible.

2. The official preparations and doses of iodine and the iodides are: Iodine, one-tenth of a grain; compound solution of iodine, three minims; tincture of iodine, one and a

half minims; potassium iodide, seven and a half grains; sodium iodide, seven and a half grains; ammonium iodide, four grains; strontium iodide, seven and a half grains; zinc iodide, one grain; diluted hydriodic acid, fifteen minims; syrup of hydriodic acid, one dram.

Iodine is used externally (as tincture) as a disinfectant, also as an irritant, counterirritant and parasiticide. Internally it has been used as an antiemetic. The iodides have been used in syphilis (third stage), pleurisy, pericarditis, rheumatoid arthritis, aneurism, asthma, and in hydrargyrism and plumbism. Iodine is used both externally and internally in some cases of goiter.

3. The specific treatment for diphtheria is the diphtheria antitoxin. It is *obtained* as follows: "Diphtheria bacilli are grown in a flask containing some nutrient broth (*e. g.* meat broth), to which 0.5 per cent. of sodium chloride and 2 per cent. of commercial peptone have been added. At the end of some weeks the bacilli are filtered off, and the fluid left contains a large amount of diphtheria toxin, and it should be of such strength that .01 c.c. (1½m.) of it will kill a good-sized guinea-pig. From .02 to 1.00 c.c. (3 to 15 m.) of it is aseptically injected into the jugular vein of a horse; this produces slight symptoms. As soon as they are past a larger dose is injected, and the dose is gradually increased until 100 c.c. (25 fl. dr.) or more are given at each injection. This leads to the formation of a large amount of antitoxin in the blood serum. At the end of some months the horse is bled to 8 liters (quarts) in a sterilized vessel, the blood coagulates, and the antitoxic serum is put into sterilized bottles and hermetically sealed, a little phenol or other antiseptic being added to prevent decomposition." (Wilcox's *Materia Medica*, etc.) The dosage is 3,000 units; the immunizing dose is 500 units. The antitoxin is injected with a syringe on the side of the abdomen or between the shoulders, under strict aseptic precautions.

4. The *official bromides* are: Ammonium bromide, dose gr. v; calcium bromide, dose gr. xv; lithium bromide, dose gr. xv; potassium bromide, dose gr. xv; sodium bromide, dose gr. xv; strontium bromide, dose gr. xv; zinc bromide, dose gr. ij.

5. Potassium acetate and citrate, and lithium citrate are administered to render the urine alkaline. They are given in a large amount of water. The dose of the potassium salts is gr. xxx; of the lithium salt gr. xv. The indications are: Too acid urine; lithemic conditions; rheumatic conditions; and generally when the urine requires to be diluted.

6. Ergot. The *official preparations* with doses are: Ergot, thirty grains; extract of ergot, seven and a half grains; fluidextract of ergot, thirty minims; wine of ergot, two drams.

*Physiological action:* Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative, it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

*Indications for the therapeutic application:* To promote uterine contractions during third stage of labor; fibroids, menorrhagia, post-partum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

7. *Silver salts, with doses:* Silver nitrate, gr. 1/5; silver oxide, gr. j; silver cyanide, gr. 1/30; unofficial salts, are: Silver iodide, gr. ½; argyrol, gr. vii.

*Therapeutic uses of silver preparations:* As a caustic for septic processes, boils, and phlebitis; for gonorrhea; for bedsores; in gonorrheal ophthalmia; also as a prophylactic; in dysentery or diarrhea; for ulcers of mouth, stomach, or intestines.

Nitrate of silver is used *externally* for: Conjunctivitis; granular lids, pruritus of genitals or anus; inflammations of the mouth, pharynx, fauces; orchitis, and epididymitis; and to prevent the pitting of smallpox; it is also said to abort bedsores and boils. *Internally*, it is used: In chronic gastric catarrh, gastritis, and gastric ulcer; intestinal ulceration, epilepsy, and chorea. The *ontidote* is sodium chloride.

8. *As compared with digitalis, strophanthus* acts quicker, is less enduring in its effects, is less certain, is not cumulative, has less marked vasoconstrictor effects, has greater diuretic power, and is said to be safer for aged patients.

The dose of tincture of strophanthus is ♏viij; of tincture of digitalis, ♏xv.

9. Ammonium preparations.—Externally: Rubefacient, vesicant, for bites of insects. *Internally:* As a gastric, cardiac, or general stimulant; as an expectorant; in hepatic disorders; muscular rheumatism; as a diaphoretic and diuretic.

*Preparations and doses:* Spirit of ammonia, ♏xv; ammonia water, ♏xv; carbonate of ammonia, gr. iv; aromatic spirit of ammonia, ♏xxx; ammonium chloride, gr. vij; solution of ammonium acetate, ʒiv; ammonium benzoate, gr. xv; ammonium iodide, gr. iv; ammonium salicylate, gr. iv; ammonium valerate, gr. vij.

10. Veratrum viride. *Preparations:* Fluidextract of veratrum, dose 1½ minims; tincture of veratrum, dose 15 minims.

*Physiological actions:* "On the skin it causes tingling, numbness, and anesthesia, and, applied to the mucous membrane of the nose and throat, violent sneezing and coughing. Internally it produces gastrointestinal irritation, prolonged relaxation of striped and cardiac muscle, reduction of arterial pressure, depression of respiration, convulsions from stimulation of the spinal cord, free diaphoresis, and reduction of temperature."

*Therapeutical action:* "As a circulatory depressant, given early, in croupous pneumonia, pleurisy, hepatitis, maniacal delirium, etc., with strong, bounding pulse and other sthenic conditions; in puerperal convulsions and the early stage of peritonitis, phlebitis and other inflammatory affections of the puerperal state; also acute rheumatism, tonsillitis, aneurysm, and wounds of the head, pericardium and peritoneum."—(Wilcox, *Materia Medica.*)

HISTOLOGY.

1. "*The spinal cord in transverse section* consists of white matter externally, and gray matter internally. The gray matter consists of a crescent-shaped portion in each lateral half of the cord, united by an intervening process, the posterior or gray commissure. Each crescent has two cornua, an anterior, thick and short, not reaching the surface of the cord; and a posterior, long and slender, reaching to the posterolateral fissure, just before reaching which it becomes enlarged (*caput cornu*), and becomes less opaque (*substantia gelatinosa* of Rolando). The size of the gray crescents varies in different parts of the cord, being largest in the cervical and lumbar enlargements. In the upper dorsal region there is a projection of the gray matter on the outer side of the crescent between the anterior and posterior cornu, called the intermediolateral tract or lateral cornu.

The white matter encloses the gray matter in each lateral half of the cord, except where the posterior cornu comes to the surface. The portion of white matter between the posterior or gray commissure and the anterior median fissure constitutes the anterior or white commissure." (*Aids to Anatomy.*)

2. *Cerebral cortex:* "The gray matter on the external surface of the cerebrum, the cortex, is divisible into five layers, whose distinctness varies in different regions, being perhaps most marked in the parietal lobe; but in the posterior portion of the occipital lobe, in the gray portion of the hippocampus major, in the wall of the fissure of Sylvius, and in the olfactory bulb this arrangement does not exist. These layers are: (1) *Molecular Layer.*—This is the most superficial, and consists of neuroglia, a few small ganglion-cells, and a network of non-medullated and medullated nerve-fibers, the latter forming a delicate white lamina absent in contact with the pia mater. The non-medullated fibers have their origin principally in the small pyramidal cells of the second layer, but also come from the dendrites and axis-cylinder processes of the cells of the first layer. The nerve-cells of this layer have two or three axis-cylinder processes arranged horizontally, which terminate by arborization in this superficial layer. (2) *Small Pyramid-cell Layer.*—The cells of this layer are small and pyramidal, having a diameter of about 10 μ, with their long axes vertical to the surface of the convolutions. Their dendrites pass into the first layer; their axis-cylinder processes passing off from the base give off collaterals and form projection-fibers which go to the corpus striatum. (3) *Large Pyramid-cell Layer.*—This layer is characterized by being made up of pyramidal cells larger than those of the second layer, and increasing in size from above downward, reaching a diameter of 40 μ. The axis-cylinder processes of these cells give off collaterals and pass into the white substance of the brain, where they become medullated. (4) *Polymorphous-cell Layer.*—The cells of this layer are irregular in shape, each giving off several dendrites and an axis-cylinder process. Some of these processes pass into the white center, while others pass to the first layer and are contained in one of its fibers. (5) *Fusiform-cell Layer.*—In this layer are spindle-

shaped or fusiform cells. In the inner half they are numerous and arranged parallel to the surface. The claustrum is made up of this layer, separated by white substance from the other gray matter." (Raymond's *Physiology.*)

3. The *pineal gland* is situated in the brain, behind the posterior commissure and in a depression between the two superior corpora quadrigemina. It is covered by the velum interpositum. It consists of follicles lined by epithelium and connected by connective tissue. The follicles contain brain sand and a viscid fluid. It is considered by some to be an atrophied third eye.

(*To be Continued.*)

## Books Received.

*The* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

KRANKHEIT UND SOZIALE LAGE. By Dr. M. MOSSE and Dr. G. TUGENDRICH. Paper; illustrated. J. F. Lehmans, Munchen.

TEXTBOOK OF OPHTHALMOLOGY. By Dr. PAUL ROEMER. Translated by Dr. MATTHIAS LANCKTON FOSTER. Volume III; cloth; illustrated; price $2.50 net; 896 pages. Rebman Company, New York.

THIRTY-SECOND ANNUAL REPORT OF THE STATE DEPARTMENT OF HEALTH OF NEW YORK (For the year ending December 31, 1911). Cloth; 1,232 pages; illustrated. The Argus Company, Albany.

MALARIA, CAUSE AND CONTROL. By WILLIAM B. HERMS, M.A. Illustrated; cloth; price $1.00 net; 163 pages. The Macmillan Company, New York.

DIE LEBERKRANKHEITEN. By C. A. EWALD. Illustrated; paper: price 11 marks; 275 pages. Georg Thieme, Leipzig.

TRAVAUX SUR LA NOUVELLE BACTERIOLOGIE DE LA TUBERCULOSE. By J. FERRAN. Paper; 173 pages. La Renaizensa, Barcelone.

DIE BEHANDLUNG DER LUNGENTUBERKULOSE IN HOCHGEBIRGE. By Dr. O. AMREIN. Paper; 16 pages; price 1 mark. Emil Abigt, Wiesbaden.

VERÖFFENTLICHUNGEN DER ROBERT KOCH-STIFTUNG. Parts V to VII by Prof. Dr. F. SCHIECK. Paper; price 9 marks; illustrated. Georg Thieme, Leipzig.

CHLORIDE OF LIME IN SANITATION. By ALBERT H. HOOKER. Cloth; 231 pages. John Wiley & Sons, New York.

THE CITY THAT WAS. By STEPHEN SMITH, A.M., M.D., LL.D. Illustrated; 211 pages; price $1.25; cloth. Frank Allaben, New York.

HYGIENE OF THE NURSERY. By LOUIS STARR, M.D., LL.D. Eighth edition; illustrated; cloth; 331 pages; price $1.00 net. P. Blakiston's Son & Company, Philadelphia.

THE ILLNESS AND DEATH OF NAPOLEON BONAPARTE. By ARNOLD CHAPLIN, M.D. Illustrated; cloth; price 70 cents; 112 pages. Hirschfeld Brothers, London.

KOMPENDIUM DER RÖNTGEN-THERAPIE. By Dr. H. E. SCHMIDT. Paper; illustrated; price 5 marks; 227 pages. August Hirschwald, Berlin.

DIE SPEZIELLE CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. By Dr. L. KATZ, Dr. H. PREYSING, and Dr. F. BLUMENFELD. Paper; illustrated; price 7 marks. Curt Kabitzsch, Wurzburg.

LA NEVROSI TRAUMATICA. By Prof. ALBERTO SALMON. Paper; 219 pages. Unione Tip.—Editrice Torinese, Torino.

INDEX-CATALOGUE OF THE LIBRARY OF THE SURGEON GENERAL'S OFFICE, UNITED STATES ARMY. Vol. XVII. Second series; 788 pages; cloth. Government Printing Office, Washington.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. By Various Writers. Cloth; third edition; Vol. I; illustrated; 928 pages; price $4.00 net. William Wood & Company, New York.

MEDICAL LABORATORY METHODS AND TESTS. By HERBERT FRENCH, M.A., M.D., F.R.C.P. Third edition; leather; price $1.50; 202 pages; illustrated. Chicago Medical Book Company, Chicago.

DER EINFLUSS DER ERWERBS UND ARBEITSVERHÄLTNISSE DER TABAKARBEITER AUF IHRE GESUNDHEIT. By Dr. THIELE. 87 pages; paper; price 2.40 marks. August Hirschwald, Berlin.

## Miscellany.

**The Progress of Surgery.**—*Medicus Peregrinus* notes that few professions have so gained in distinction as has that of surgery. Its progress in this respect is something like that of the dog, always an object of the basest contumely in Homeric time, but now risen in caste until recognized as one of the noblest animal friends of man. The barber-surgeon in early days was unceremoniously booted about camp or court, and admitted to the company of his betters only when he was desired to discharge his mystery. Gradually his growing knowledge enabled him to command more respect, but even in the Middle Ages he was only an upper servant. By this time, however, the surgeon divorced himself from the barber and evolved into a separate entity. Anesthesia and bacteriology have completed the emancipation of the surgeon and have placed him on a pedestal of eminence.—"Men, Manners, and Medicine."

**Errors in Practice.**—T. F. Reilly comments upon this subject as follows: "If by any chance you have made an error, either in diagnosis or treatment, do not be overanxious to admit it. Don't say anything; certainly do not volunteer the information that it was your fault. You are infallible to most of your patients. You may think the people applaud your candor and sincerity, but they will always treasure your mistakes up against you. When they become your enemies, you will hear to your mortification of how you yourself admitted such an error. Honesty and candor are not synonymous terms. You should be honest, but honesty does not imply that you must unnecessarily expose your weaknesses to everyone."—"Building a Profitable Practice."

**Some Oddities in Nomenclature.**—In the Section on the History of Medicine of the Royal Society of Medicine, B. Glanville Corney recently read a paper on this subject. He said that in Rio de Janeiro during the epidemics of influenza which occurred in 1777 and 1802-3 the disease was called "zamporinion" and "corcunda." He also cited an epidemic of dengue which ran through Brazil in 1847 and was called "polka" at Rio and "rabo aherto" at Bahia. The term "zamporinion" was adopted from the name of a Venetian singer who was popular at Rio at the time, and has nothing to do with the Portuguese name for measles, "sarampao"—in Spanish, "sarampion"—which is directly derived from the Greek, the bright color of the rash resembling that of a faded vine leaf. "Corcunda" means hunchbacked, and came into popular use because of the bent condition in which patients were left at the end of each paroxysm of cough, which was said to be of a very spasmodic character and closely to resemble whooping-cough. Dengue was called "polka" because of a distinguished court beauty at Rio who was a native of Poland and was in great vogue at Bahia at the time of the epidemic. The same epidemic received the name "rabo aherto" because there chanced to be coincidently an unusual glut of the fish of that name. Glanville Corney advanced the theory that an epidemic of cerebrospinal meningitis was coincident with the Bahia epidemic and that whooping-cough played a part in the "corcunda" attack. He also alluded to the older folk names for influenza—namely, "le tac," "the new delight," and the "jolly rant," which have in turn displaced each other and have themselves been replaced by "the flue."—*British Medical Journal,* February 8, 1913.

### THE PATHOGENESIS OF THE GASTRIC CRISES OF TABES.

BY E. CASTELLI, M.D.,

NEW YORK.

CONSULTING PHYSICIAN TO THE COLUMBUS HOSPITAL; ATTENDING NEUROLOGIST TO THE POST-GRADUATE; VISITING NEUROLOGIST TO THE NEUROLOGICAL HOSPITAL; ADJUNCT PROFESSOR TO THE POST-GRADUATE SCHOOL.

AND

T PINEL, M.D.,

PARIS.

CHEF DE CLINQUE OF PROFESSOR DÉJERINE AT THE SALTPÉTRIÈRE.

THE unsatisfactory results obtained in the medical treatment of the gastric crises of tabes have induced the neurologist to try surgical treatment. It is certain that the gastric crises constitute very often one of the most serious accidents of tabes; the violence and the repetition of the crises, the abundance of the vomiting, the absolute impossibility of nourishing the patient during the persistence of the crises, the deep denutrition resulting, the morphinism—inevitable consequence, are all causes that justify the surgical attempts, even the most daring ones. The first attempts were made on the stomach itself or on its nervous plexus, but the gastroenterostomy practised at the beginning seems now to be entirely abandoned as inefficient and not rational; the interventions acting on the plexus cæliacus or on the gastric nerves do not seem to have met with better success. Vallas, foreseeing the technique of Taboulay, practised the elongation of the solar plexus. The patient was well during two years, after which the crises reappeared. The operations acting on the pneumogastric are still small in number. Esner proposed the section of the pneumogastric at the level of the cardias. His first operation was a success, and still three months after the patient seemed recovered; the second observation, on the contrary, was followed by death after three weeks following the atonic dilatation of the stomach, accompanied by pains as violent as before but without vomiting. We must add that this operation is not a simple one, because the usual result of the section of the pneumogastric is the paralysis of the stomach with gastric hyperacidity and reflex contracture of the pylorus (Fritch) and very often the production of ulcerations (Ziron, Van Yseren, Ophüls). In order to avoid these troubles Esner is compelled to associate to the resection of the pneumogastric a gastrotomy and the introduction of a drainage through the pylorus reaching the duodenum.

The surgical intervention acting on the posterior roots of the dorsal region seems at present to be the only rational one. These are the surgical interventions which will be the object of our observation. At the present time these are the proceedings used in order to reach the posterior roots: The Foerster, the Guleeke and the Franke operation. Foerster first of all had Kuttner perform the intradural section of the posterior roots in order to interrupt the painful reflex whose sensory route passes without any trouble through the splanchnic fibers and through the dorsal posterior roots. At the beginning the posterior roots cut were the 7th, 8th, 9th and 10th, but following several recurrences Foerster advises at present to pass *above* the *5th dorsal* and *below* the *12th* to avoid the intestinal painful crises.

We can from the beginning be convinced of the manifest danger of the operation. There exist reports of about fifty cases of gastric crises operated upon by this method.

Kuttner: 3 cases; 1 complete recovery, 1 recovery 5 weeks old, 1 death by infection.

Tietze: 1 case; 1 recovery 10 weeks old.

Moskositzy: 1 case; 1 recovery 6 weeks old. The patient has gained 8 kg. since the operation.

Flaerke and Tick: 2 cases; good results.

Baeker and Heule: 1 case followed by paralysis of the inferior limbs, paralysis of the bladder.

Breren de Kan: 1 case; disappearance of crises.

Guleeke: 5 cases; 1 death from pneumonia (operation intradural) 4 cases (operation extradural) with the following results: (a) 1 case with disappearance of the gastric crises; (b) 2 cases in which gastric crises disappeared but intestinal crises followed the operation. (c) 1 case with negative result, notwithstanding the resection of the posterior roots from the 7th to the 11th.

Clairmont: 5 cases; 3 ameliorations.

Groves: 3 cases.

We must add to these a list of cases given by Bruns and Sauertret, Thomas and Nichols, Morinzer, Schlesinger, Schaffer, Federman, Lewandowsky, Nonne, Bornhaupt, Lambert, Leruhe, Cotte, Sothersen, Van Angerer (3 cases), Neile, Rosenstein, Zinn and Meishaw, Byron, Bramwell and Thompson, Anselme Schwartz, Tupper, Labey.

The observations of Hovelacque on 49 cases gives as results 10 cases of rapid death of which 7 resulted from infection; 1 death from shock; 2 from bladder complications. To these results we must add 3 deaths from myelitis in the following month, 5 cases of postoperative paraplegia; several cases of bladder troubles; 3 recurrences of crises; 1 case of recurrence with aggravation; in 1 case the crises disappeared but were followed by atony of the stomach necessitating a gastroenterostomy.

We must add that a certain number of patients disappeared without being kept track of. So, in summing up the cases of death, paraplegia and recurrences, we find 23 unsuccessful results; over 49 operations with a mortality of 26 per cent. This mortality is due to a complex of causes, viz., to the operative shock, to the meningitis, to the bladder

complications, to the loss of cerebrospinal fluid, and also to the state of the cachexia of the patients operated upon. That will explain why the mortality is higher in the operation for gastric crises than in the one practised only by Foerster on the posterior roots of the lumbar region in the cases of spastic paraplegia. So the Foerster operation for gastric crises is a serious one and justified by the gravity of symptoms presented by the patient.

As far as its usefulness is concerned, it may be considered real. In the majority of cases, after the

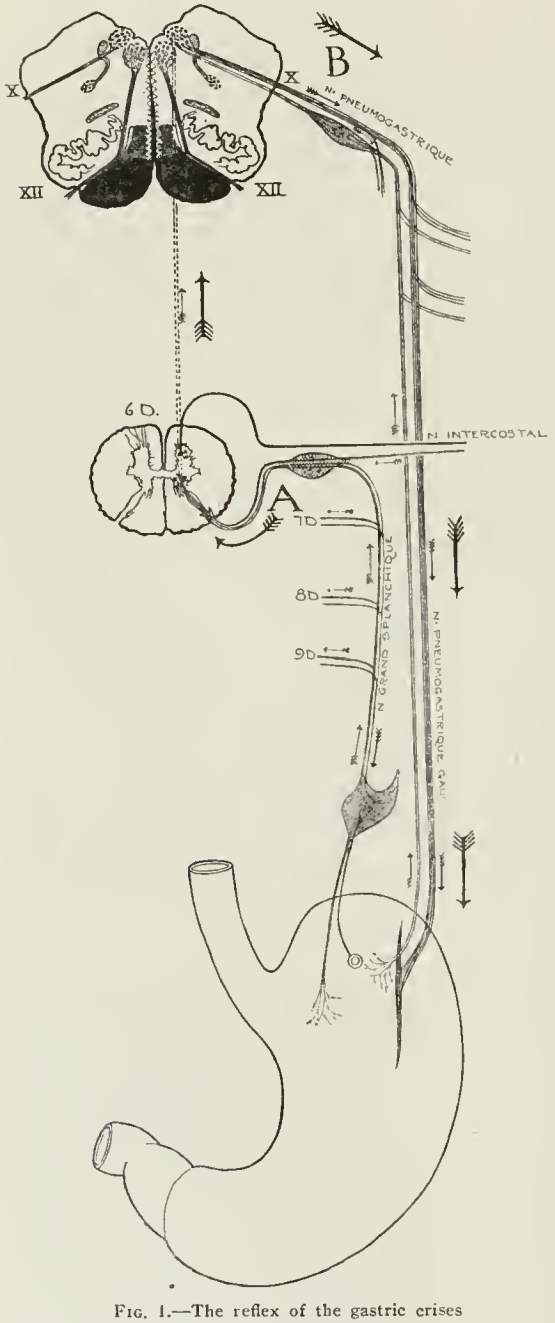

Fig. 1.—The reflex of the gastric crises

operation the gastric crises disappear, nourishment becomes possible, the weight of the patient increases but very often intestinal painful crises persist. The case of recurrence or of negative result seems due to the insufficient number of roots exposed. There is, in fact, a very interesting observation of Guleeke in which the crises returned after the resection of the 7th, 8th, 9th dorsal roots but disappeared after a complementary resection of the 10th and 11th roots.

The gravity of the Foerster operation seems principally due to the opening of the dura mater and to the exit of the cerebrospinal fluid. So it is easy to understand that the first modification brought to the technique of the operation was the one allowing the operator to reach the root per *vias extradurales*.

Guleeke, after a case of death following a Foerster operation proposed and performed the extradural resection of the posterior roots and in so doing he avoided the exit of the cerebrospinal fluid, the collapse following the intervention, and avoided also the secondary meningeal infection. After the resection of the veterbral arches, Guleeke takes hold of the dural sac in the middle and brings it on one side and cuts the roots of the opposite side with a rapid dissection, separates the anterior from the posterior root, opens the conjunctival sac for a length of a few millimeters, cuts the posterior root which retracts immediately towards the medulla, applies a fine ligature at the base of the sheath, and cuts the peripheral segment.

Notwithstanding its undeniable advantage over the Foerster operation and the satisfactory results, the Guleeke operation represents a really difficult operation. Pausset, who studied the technique of intervention, warns against the long duration of the operation and the abundant hemorrhage. It is easy to understand the difficulty of cutting the posterior root in its conjunctival sac, in the midst of the spinal intradural plexus so developed at this point.

Franke, on his part, proposed a very interesting modification. He performed on a patient refusing the Foerster operation, the bloody extirpation of the 6th, 8th, and 9th intercostal nerves; the nerve uncovered near the vertebral column, separated from the muscular masses, taken with a clamp, and gradually detached from its center, rolling its extremity on a clamp; this detachment, according to Franke, must in the meantime pull and dislodge the roots of the splanchnic nerve, viz., the rami communicantes which branch off from the intercostal nerve immediately below the spinal ganglion; in fact, very often the severing detaches, besides the intercostal nerve, a small fragment of the spinal ganglion. In a first case Franke obtained real success complete in appearance because his patient seemed to have entirely recovered from the crises during a period of 18 months after the operation. A certain number of surgeons have since Franke attempted the operation—Clermont, Mario and Pasturie, Cade, Leruhe Mourquod and Cotte—but the results have been very variable. In a case of Clermont, the gastric crises suppressed during a few weeks reappeared afterwards. In the three cases of Mario and Pasturie the crises have disappeared and the patients have been considered recovered. The case of Cade and Leruhe Mourquod are of too recent a date to form an opinion. At the Salpetrière the Franke operation has been performed three times: in one case with recovery in eight months; one with recurrence, a third with death.

The observation of these three cases has been studied by T. Pinel of the Clinic of Professor Déjerine and it is in studying with him the specimen of the autopsy of the one case that we have been able to develop the ideas exposed in this paper.

The Franke operation apparently so benign is not as simple as it seems. It is almost impossible, in fact, in uncovering the intercostal nerve to avoid the formation of a double pneumothorax. It is certain that this pneumothorax is usually endured well, but in a case of death observed at the Clinique

Charcot it seems to have been the cause of the death. We will see now in making use of an autopsy performed on a patient that had been operated with the Franke method that the operation seems at least theoretically incomplete, insufficient, and not rational.

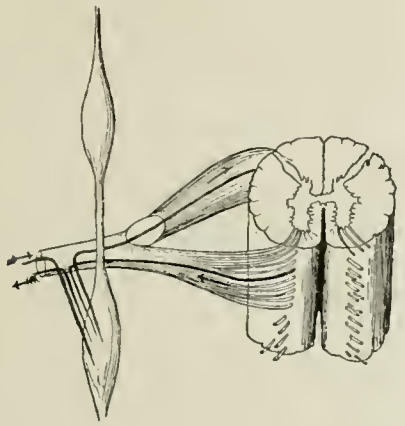

Fig. 2.—Showing the anatomical relations of the anterior and posterior roots

Let us now try to explain the probable mechanism of the tabetic crises and with the help of the pathogenic notions acquired judge of the value of their different operations.

As Foerster has already stated, the gastric crises are essentially constituted by three elements: (a) Pains, (b) vomiting, (c) troubles of secretion.

But these three elements composing the classic syndrome of the gastric crises do not always exist together. The clinic shows that a dissociation of the elements of the syndrome may take place and we may, for instance, have painful gastric crises without vomiting, while we almost never have vomiting without pain.

It is then an ascertained fact that the pains are the essential and initial phenomena, while the vomiting and the troubles of secretion are only the reflex reaction responding to a painful irritation.

Vomiting and the troubles of secretion manifestly originate from the pneumogastric nerve, which is the principal nerve of the stomach and whose irritation, as physiology teaches, determines contraction of the stomach and hypersecretion, the pneumogastric being essentially the nerve presiding in the function of vomiting. The pains instead seem not to originate from the irritation of the pneumogastric, as this nerve takes only a very small part in the sensitive innervation of the stomach; and also the recent works of Muller and Newman have a tendency to put in doubt its rôle as sensitive nerve of the stomach.

Besides, it is easy to conceive that a stimulation of the sensitive branch of the pneumogastric at its point of exit from the skull (at the level of its meningeal sheath) would determine at the same time gastric, esophageal, laryngeal, cardiac, and pharyngeal pains, viz., pains in all the dominion of the irritated nerve. We must then admit a pneumogastric origin of the gastric crises of tabes only in the case in which the pharyngeal and laryngeal apparatus participate in the crises.

The sensory innervation of the stomach is almost essentially given by the splanchnic nerves which are constituted by the rami communicantes of the dorsal roots from the 5th to the 10th as it has already been demonstrated by Head, Newman, Muller, Laignel, Lavastine-Eppinger, and Hess.

The sensory fibers of the splanchnic nerves after having been intercepted in the spinal ganglion reach the medulla through the posterior roots and can consequently participate to the painful irritation of these roots?

If we resume the anatomical data of the great splanchnic we know that it is constituted by two orders of fibers, viz., of thin amyeline fibers in considerable number, and of a small number of large myelinic fibers; and that these two kinds of fibers have two absolutely distinct functions. The small one, without myelin, are centrifugal fibers, coming from the medulla, probably from the peri-ependymal, gray matter or from the base of the anterior cornua; they leave the medulla with the posterior roots, they pass through the ganglion without interrupting their continuity, and they continue their course in the splanchnic.

In fact, it has already been demonstrated by Jean Charles Roux that if we examine the grand splanchnic nerve of the tabetic, we will find a certain number of these fibers degenerated; in the same way if experimentally we cut the posterior roots we will see them degenerate toward the splanchnic. They are consequently centrifugal and have their trophic center in the medulla and not in the ganglion. Their function is not well known; they certainly are not sensitive functions but their experimental stimulation will not give motor phenomena of the stomach. Perhaps they are vasomotor fibers. At any rate, their irritation in the tabetic at the moment in which they pass in the posterior roots cannot be considered the origin of the gastric pains; it may be that their irritation provokes vasomotor troubles; it may perhaps be that their irritation in suppressing their inhibitory rôle makes easier the reflex reaction of the pneumogastric, manifesting itself by the vomiting.

The large myelinic fibers instead do not degenerate after the section of the posterior roots, but they degenerate if the spinal ganglion is excised. They are sensitive fibers and Kölliker experimenting on the mesentery of the cat, has seen these fibers end in the Pacini corpuscules. In the tabetic when we examine the dorsal posterior roots we find these sensory fibers degenerated but if we cut the great splanchnic we find them intact; consequently their

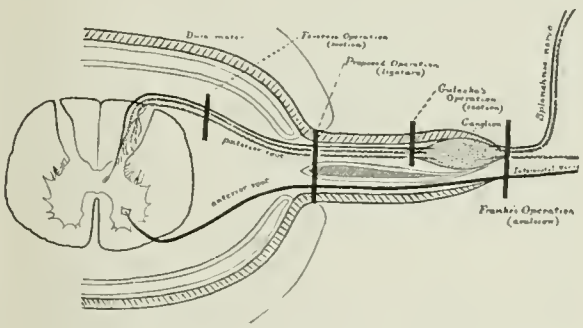

Fig. 3.—Showing the different operations performed for the gastric crisis of tabes.

painful irritation and their destruction takes place between the spinal ganglion from which they originate and the medulla, viz., in the root itself. It is to these fibers that in our estimation we must relate the harmful irritation determining the gastric crises.

But besides the anatomical argument in favor of the dorsal origin of the gastric crises, we have also clinical arguments confirming the anatomical views. We observe in fact during the crises, and sometimes even during the interval between the crises, troubles of sensibility in the domain of the intercostal nerves between the 4th and 10th roots.

We notice either an anesthesia or a hypoesthesia and sometimes a very painful hypoesthesia. It is a phenomenon more or less constant that we have found always and to which Foerster, Guleeke, Mario, Pasturie, Lermier have very often called our attention. And besides we can make a crisis disappear, as Loring has shown in injecting in the muscular masses covering the origin of the intercostal nerves a solution of cocaine.

It seems then demonstrated that the gastric crises are secondary to the painful irritation of the dorsal roots which furnish both the sensibility of the intercostal nerves and the sensitive fibers destined to the gastric mucous membranes. The simultaneous irritation of these fibers results by producing intercostal pains and gastric pains which start the bulbar reflex of vomiting. All interventions, which, taking this point of view as departure, will attempt to approach the dorsal roots, are perfectly legitimate and the only rational ones.

*Recapitulation.*—We have established the splanchnic origin, and consequently the dorsal radicular origin of the tabetic pains which determine the gastric crises. We must now ask at which point are affected and irritated the sensory fibers of the stomach.

The large myelinic fibers of the splanchnic are intact in the nerve and degenerated in the posterior root; if we cut longitudinally a dorsal ganglion and its posterior root we notice that this degeneration goes as far as the superior pole of the ganglion, where it ends; on this point a large fibrous thickening and an accumulation of inflammatory cells exist; it is the process of transverse radicular neuritis to which, after the studies of Nayeotte and Tinel which must connect the tabetic troubles and disturbances. We can see on the microscopical specimen and on the schema, that the meningeal radicular sheath is the seat along all the length of the posterior root of a chronic irritation which is not found in any other place as marked and that consequently seems to be the point of departure of the painful irritations and of the destructive lesions. We can, besides, through the kindness of Professor Déjerine give here the photographic reproductions of the same microscopical section of a very important case of tabetic gastric crises, studied in his laboratory. We see very well that the degenerative lesions are almost entirely situated on the roots of the dorsal region from the 2d to the 6th dorsal; in this case of tabes terrible gastric crises existed. So the dorsal systematization of the gastric crises seems demonstrated.

Let us see now how we can justify in connection with these anatomical and physiological data the different operations proposed.

*Foerster Operation.*—The section of the posterior roots seems the most logical and rational; it certainly severs the reflex connection between the irritated roots and the bulbar centers; perhaps the operation has not until now been practised over a sufficiently large surface. After having counted the operation to the 6th, 7th, 8th, and 9th roots Foerster entered the operation above as far as the 5th below to the three last dorsal; it would be necessary in our estimation to extend the section as far as the fourth, which, in some cases seems to furnish a sufficiently large contingent of fibers to the great splanchnic. It seems, in fact, that the recurrences and the failures of Foerster operations principally are only due to the insufficient number of roots cut.

*Franke Operation.*—It seems less logical and rational, in fact the severing of the intercostal nerves is a blind maneuver which gives only very variable results, because it happens that sometimes the intercostal nerve breaks immediately while at other times it breaks at a point a little further from the starting point; but it is very rare to be able to sever in the meantime the inferior pole of the ganglion; so it is only in this circumstance that, according to Franke himself, we could be sure of the severance of the origin of the splanchnic. We know only one case, the one of Cotte and Leridie, in which the severing of the nerve has brought with it at the same time the spinal ganglion and also the posterior root, and also in this case the fact has only been noticed in one root.

Even admitting, then, that through the Franke proceeding we could extirpate with surety the inferior pole of the spinal ganglion, it is evident if we consider the anatomophysiological data exposed above, that in so doing we do not reach the tabetic lesion—which, as was stated, is not located below but above the spinal ganglion, in the vascular meningeal sheath. It is this location that we must reach. So the Franke operation seems at least therapeutically illogical and blind, and we must add also that notwithstanding the benign appearances the operation is not devoid of danger because of the pneumothorax that almost inevitably follows the operation. Still, it seems already clinically established that the operation has brought a certain number of temporary ameliorations and some recoveries; but we must remember that nothing is more capricious in its evolution than the tabetic gastric crises.

The gastric crises are generally an early symptom in the evolution of tabes and are not a durable symptom. It is not rare to observe cases of tabetic gastric crises having lasted for years suddenly completely disappear without any therapeutic intervention. Their disappearance is without any doubt due to the complete destruction of the posterior dorsal roots, accomplished by the natural evolution of the disease. It is also possible that the traumatism of the Franke operation and the hemorrhage that the operation produces in the ganglion favors the complete destruction of the irritated fibers and is capable of producing the disappearance of the crises; it may be also that the considerable hemorrhage acts as a local revulsif. In fact, all of us have in part seen the painful gastric crises of tabes relieved by the application of cups applied on each side of the vertebral column. The Franke operation shows a statistic of a great number of failures and recurrences which demonstrate the logic of our criticism.

There remains the Guleeke operation. This is evidently less dangerous than the Foerster, being also as logical because it aims to the incision of the posterior roots, above the ganglion, but it is a more difficult one. The section of the posterior roots in the meningeal involucrum is a long and very delicate work, and we may add that it seems to us absolutely useless. In fact, the Franke operation has at least demonstrated that the cutting of the inter-

costal nerves and the severing of the vasi-communicantes is absolutely harmless, consequently there would be no inconvenience in cutting or suppressing at the same time the anterior and the posterior root. This would be the proceeding that Dr. Pinel, and myself would suggest, consisting in the ligature of the two roots, anterior and posterior, as far as possible from the ganglion.

This ligature could be performed very rapidly after laminectomy without any work of dissection; to this ligature we may add the section of the two roots, but this would not be necessary. We reach in this way with certainty the tabetic radicular lesion; we intercept completely the reflex connections between the sensory ganglion and the medullary centers, and we do not expose the patients to the dangers of infection of the meningeal cavities because of our avoiding the exit of the cerebrospinal fluid.

---

## NEWER IDEAS CONCERNING THE PROBLEM OF CANCER ETIOLOGY.*

By LEVERETT DALE BRISTOL, B.S., M.D

SYRACUSE, N. Y.

ASSISTANT PROFESSOR IN CHARGE OF BACTERIOLOGY COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY.

Although cancer research is being carried out in most communities where the Science of Medicine is studied and practiced, we have as yet, after many years of toil, been unable to find its true cause. Most of our knowledge of its etiology is expressed in the theories of different workers on the subject, supplemented to a certain extent by a mass of more or less important facts gleaned by experimentation.

In presenting this subject for your consideration I propose first very briefly to review and criticize the older theories of neoplasia, and will then call your attention to some of the most recent facts and fancies brought out concerning the causes of new growths, at the same time suggesting some original ideas on the subject.

Throughout this paper, unless otherwise noted, the word "cancer" will be used to cover *malignant* neoplasms in general.

Let us briefly consider the older theories of Cohnheim, Ribbert, von Hansemann, Adami, Hauser, Oertel, and Marchand, and the so-called "parasitic theories."

According to Cohnheim's theory (one of the most popular) a neoplasm originates in displaced embryonic cells or "rests." While this may be true in some cases it cannot explain the origin of all kinds of tumors, a requirement which Adami[14] justly insists upon. Furthermore this theory does not explain the reason for, nor the stimulus to, a sudden division of these supposed cell "rests."

Ribbert believed that a cell displacement is necessary but that a tumor results because of a decrease in the external resistance and forces which oppose the growth of cells. This theory does not meet Adami's requirement and does not reveal the cause for the sudden change from the normal to the abnormal.

Van Hansemann's theory of anaplasia suggests that certain abnormal cells exist which have an increased vegetative activity but are unable to attain normal structure and functions. This he believes is due to an abnormal distribution of nuclear material in the cells. Again this theory is applicable only to malignant tumors, and suggests no stimulus.

Adami[14] tells us that cancer may be due to cells losing their habit of function and acquiring the habit of growth—at which point the neoplasm starts. This gives us no idea of what the force might be that could cause such a changed condition.

Hauser's theory would lead us to believe that certain cells—descendants of the ovum—may show a variation from the normal in a very much more active vegetation than their related cells, just as there may be marked variation in one species of animals, plants, bacteria, etc. The descendants of such cell variables would form a neoplasm. This is too much a question of heredity and predestination and does not explain those tumors which follow, in close association, injuries and irritations.

Oertel states it as his belief that two orders of chromatin exist in the single nucleus, one governing function, the other influencing growth. A cancer cell, he believes, is one which has lost the chromatin governing function, and its descendants have only the power of proliferation. This does not explain why certain cells should proliferate in a *malignant* manner, neither has it ever been proven that two such orders of chromatin are present in a cell nucleus.

Marchand[1] holds that for a malignant tumor to develop there must first be a local cell degeneration and that in some way this abnormal cell has an action on the other cells in the neighborhood causing them to take on a malignant proliferation. Although he describes no detailed forces which might be concerned in such an action, his theory seems to be strengthened by recent investigations.

That cancer is caused by a microorganism or parasite is a view that has many ardent supporters. Practically every form of microorganism, including bacteria, protozoa[18] and animal and vegetable parasites, has at one time or another been accused of being the cause of cancer. Up to the present time no specific parasite has been found, of all those suspected, which could experimentally reproduce a true cancer. Walker[2] of Buffalo has recently published an article in which he believes he has demonstrated that cancer is produced by a parasite of the earthworm. Fibiger[19] of Copenhagen reports that he has induced cancer in rats by feeding with parasites of cockroaches. To me the very multiplicity of parasites "demonstrated" to be the specific cause of cancer is the greatest argument against the theory. On the other hand, we may include any or all of these microorganisms as predisposing causes leading to the precancerous stages of cell degeneration or disordered metabolism, admitting at the same time that many other entirely different forces may lead to the same cell derangement. It is fairly safe to predict that should a specific microorganism eventually be found as the cause of tumors (a finding which at present seems unreasonable) it will belong to the class of ultramicroscopic organisms.

All theories associated with strict morphology, biology, or bacteriology have, up to the present, failed to explain the cause or causes of cancer and other growths. It would seem, then, that the problem should be studied from a different viewpoint.

For the last year and a half the writer has spent much time in a study of the literature on the problem of cancer etiology, and on examinations of

*Read at a meeting of the Syracuse Academy of Medicine, Jan. 21, 1913.

tumor tissue from the standpoints of bacteriology, pathology, biology, and chemistry. As a result of this study he wishes to class himself with those few individuals who believe the factors at the basis of cancer are chemical or biochemical.

Of the older theories that of Marchand seems the most reasonable, and I believe that by imagining chemical or biochemical and physical forces to be applied to this theory we may have an interesting and valuable working hypothesis.

As a *primary* cause of cancer it would seem that some form of cell or tissue degeneration is necessary. Also it appears that this degeneration, which leads to necrobiosis or to necrosis, may be due to one or more causative factors which can be divided into two groups: (1) The interference with the nutrition, or blood supply to a part. (2) Cell or tissue injury, due to the following means: (a) Mechanical (wounds, etc.); (b) chemical (poisons, etc.); (c) physical (heat, light, etc.); (d) parasitical; (e) functional (overactivity, disuse). This may be termed the *primary "precancerous" stage.*

Everyone is familiar with the close association between cancer and a history of previous injury, chronic irritation or chronic inflammation. Because we can obtain no history of previous injury, chronic inflammation, or irritation in a case of cancer may we justly say that none of the above factors, some of which may be unfelt and unseen, has been the cause of a primary cell or tissue degeneration? May not certain things affecting the blood supply, certain protoplasmic poisons, heat or light rays, or bacteria have been at work in the past to cause necrobiosis or necrosis absolutely unrecognized by the diseased person. The importance of "precancerous" lesions cannot be overestimated. We owe much to Bloodgood[16] of Johns Hopkins, and others, for their emphasis of this fact.

As a *secondary* step in the chain of events leading to a malignant proliferation of cells we would mention the affinity of these primary "precancerous" areas of degeneration or necrosis for certain inorganic salts of the blood, as well as a marked change in their chemical structure and metabolic activities. This would constitute a *secondary "precancerous" stage.*

Before proceeding further let me emphasize that years ago Ringer, and later Loeb,[3] discovered that certain inorganic salts are absolutely essential for the proper metabolism, development, and reproduction of the cells and tissues of the body, and that these constituents must exist in the blood, lymph, and tissues in a constant proportion if cell activity and reproduction are to be maintained. Moore,[4] writing in a book edited by Leonard Hill in 1906, on "Recent Advances in Physiology and Biochemistry" suggests that "in an action due to variation in inorganic salts will ultimately be found the secret of the cause of irregular cell division in the body, giving rise to malignant growths." He goes no further, however, in demonstrating how this influence might be brought about.

Moore, with Roaf and Whitley, found "that a mere trace of added sodium hydrate increased markedly the growth and cell division in the fertilized eggs of *Echinus esculentus.*" Additional amounts slowed or stopped the division.

He found also that the addition of alkali caused irregularity in the size and shape of the cell, and *irregular nuclear division.* Acid had practically the opposite effect. He concludes that the living cell is extremely sensitive to variation in concentration of the hydroxl and hydrogen ions, and that a normal reaction of the medium is important for cell growth and division.

More recently Ross and Cropper[5] of Liverpool by an ingenious *"in vitro"* method, have been able to study reproduction normal, augmented, and asymmetrical," of living cells, especially leucocytes. They have been able to watch carefully the diffusion of substances into these cells from the surrounding medium and have drawn up certain laws or factors relating to such diffusion. They believe, and have demonstrated, that diffusion into cells is increased by four chief factors: (1) Concentration of the diffusing substances; (2) time allowed for the process to advance; (3) heat; (4) alkalies and alkali salts. They have also found that increasing these factors within certain limits increases the diffusion of substances into the cells from the surrounding medium. Furthermore they have concluded that the latter factor, the influence of the alkalies and alkali salts, is more important than any of the other three, and that if twice the amount of salts, up to a certain point, is added to the surrounding medium the diffusion of substances into the cells will be twice as fast. With increased diffusion they demonstrate increased growth and division of cells.

As a result of some interesting and valuable experiments done by Carrel of New York on the cultivation and development of certain body tissues in suitable media outside the body, the following conclusions have been reached: "Normal blood plasma is not the best or 'optimum' medium for the growth of tissue or organs, each of which probably has its own optimum medium not attained in the body under normal conditions. Slight modifications of the tension, the alkalinity, or the addition of certain inorganic salts to normal plasma increases the rate of growth of tissues."

If this is true of tissues, must it not be true of the individual cells of tissues? Thus we must assume that an individual epithelial cell or connective tissue cell is in a medium, the blood plasma or lymph, which under normal conditions is not influencing the rapidity of growth of such a cell as much as it really has the power of doing when the surrounding plasma or lymph has been even slightly changed in tension, reaction, and inorganic salt content. May not tumor cells be an "optimum local growth" of cells because of an "optimum local chemical medium" in which they exist? If there is a parasite which causes cancer, or any other tumor, it would seem that the *individual cancer, or tumor, cell is the parasite,* and that an influence is brought to bear on a normal cell which causes it to take on a parasitical existence. As suggested above, this is possibly a *chemical* influence from the neighborhood, or local medium in which the cell exists, and it acts by markedly changing the molecular structure and entire nature and metabolism of the cell itself, a change which is transmitted possibly to the "daughter" cells.

Abderhalden,[20] who has done such excellent and important work in the field of physiological chemistry, has the following to say on the chemical constituents of the cell and its surrounding medium in relation to cell growth and character: "it is possible that a body cell may retain its individual nature *only with difficulty* if for any reason its chemical nature and function become seriously altered, and

the progeny of such a cell will possess the characteristics of the mother cell so that gradually a whole cell complex will develop which is of a nature foreign to the entire organism and to its metabolism, and in fact the metabolic end products of this new cell complex may exert a disturbing influence upon the metabolism of the remaining cells of the body."

"Apparently there is a connection between these cells and the mother soil—we refer especially to sarcoma and carcinoma—for it has been frequently doubted whether such cells can be successfully transmitted to organisms of a different species. We are, in making these suggestions, very far from explaining the formation of these peculiar, atypical tissues. We only wish to bring forth the fact that with the further development of physiological chemical knowledge new tasks will be set, and that even problems of purely morphological investigations will, in the course of time, become closely allied to those of physiological chemistry. If it is once found possible to compare the metabolism of the cells of a cancer, or other malignant growth, with normal cells, we may certainly expect to obtain a more accurate insight into the nature of such mysterious processes."

Some of the most recent work of Carrel[6] is on the "Artificial Activation of the Growth in Vitro of Connective Tissue," an interesting account of which appears in a recent number of *The Journal of Experimental Medicine*. His summary and conclusions are, in part, as follows: "The experiments have shown that extracts of tissues and tissue juices, under certain conditions, accelerate the growth *in vitro* of connective tissue from about three to forty times. This activating power was found in many tissues. It was much more marked, however, with the extracts of embryos, of adult spleen, and of the Rous sarcoma. The power diminished directly with the dilution of the extracts, and appeared not to apply to the tissues of a heterologous animal. The power was reduced when heated at 56°C., and removed when heated at 70°C. It was diminished markedly by filtration through a Berkefeld filter and was completely suppressed by filtration through a Chamberland filter."

It has been of interest to me to look at these facts from the standpoint of the cancer problem. Here we find that normal tissue may be accelerated "from about three to forty times" not, apparently, by any microorganism, or any other factor which we have assumed as possible causes of malignant proliferation, but by a definite "stimulus" present in tissue or tissue juices, and it is difficult to conceive of this "stimulus" to growth being anything but chemical or biochemical in nature. It does not take a great stretch in imagination to believe that those forces which can cause a normal tissue to grow forty times its normal rate may also account in some way for malignant proliferation.

From the viewpoint of my ideas concerning the importance of chemical substances, including inorganic salts, in the causation of malignant growth of cells, this further statement of Carrel's is interesting: "An extract obtained by the centrifugalization of embryonic tissue, a few minutes after it had been mixed with Ringer solution, increased the rate of growth two and a half and three times. The acceleration of the growth *was much more marked* when the mixture of tissues and Ringer solution was allowed to stand in the refrigerator for twenty-four hours or several days before being centrifugalized." In one of his experiments tissue was mixed with Ringer solution and allowed to stand twenty days. This extract caused, in twenty-four hours, an area of new connective tissue thirty times larger than did the control. This would seem to indicate that the more the Ringer's (consisting of the inorganic salts NaCl, CaCl, and KCl in solution) was allowed to mix with, or act upon, the substances in the extract which caused the growth of the connective tissue, the more power this extract had for accelerating growth.

Cell reproduction is constantly taking place in the living body and it would appear that a stimulus which causes normal reproduction is either constantly present within some portion of the cell, or else it comes from outside the cell or from the surrounding cell medium by a process of diffusion, or by a definite chemical attraction, and is closely associated with the nutrition and growth of the cell, especially of the nucleus. We believe the latter is the true condition and that, as many authorities would lead us to believe, a fixed ratio between the salts in the blood, lymph, and tissues is necessary for normal acticity and reproduction of cells, and also that the chemical structure of these cells must remain intact. Is it not possible, then, that a disturbance in this ratio and an upset in the chemical equilibrium will lead to abnormal metabolism, growth, and reproduction, and result in an atypical growth in the local area involved

This increase of cell growth may be due primarily to increased permeability, of the cell membrane. McClendon and Mitchell[7] have found that "an increase of -OH ions in the surrounding medium causes an increased permeability of both fertilized and unfertilized sea-urchin eggs and leads to an increased rate of oxidation within the egg." Lillie[8] says that "an increased permeability leads to increased cell metabolism and oxidation, an upset in the chemical equilibrium of the cell, and an accelerated cell division."

From these and other sources we learn that the permeability of cell membranes, the absorptive powers, the intramolecular activities, the oxidations, and the reproductive powers and characteristics of cells may be altered through the influence of the surrounding chemical medium or environment. Acceleration in all these processes may be brought about artificially by a change in the inorganic salt content or in the amount of -OH ions in the medium.

Now we may proceed to a consideration of the pathological condition in which the local inorganic salt content is increased in areas of degeneration or necrosis due to the affinity of such areas for these salts. We know from our pathological and chemical experience that there is a somewhat definite affinity between dead and dying tissue and certain inorganic salts of the circulation, especially magnesium and calcium in the forms of phosphates and carbonates. From the beginning of the attraction between these salts and the changed tissue (a chemical pathological process which is not, as yet, thoroughly understood) is there not a gradually increasing localized salt content established? If this is so, may it not be possible that due to the influence of increased inorganic salts the cells in the immediate neighborhood take on increased permeability and absorptive powers resulting in a molecular rearrangement, a changed chemical equilibrium and a rapid growth and local proliferation compared to that in other parts of the body?

As yet we do not attempt to define any one spe-

cific substance or force as the exciter, or the inhibiter, of rapid and malignant proliferation of cells. This must be worked out by experiment. It may be simply a question of increased osmotic pressure and surface tension due to the increased absorptive powers of the cells affected, thus leading to rapid cell division. Forbes Ross[9] of London believes that cancer is due to an upset in the mineral balance of the body, especially as regards the potassium salts. He finds these potassium salts to be greatly diminished in cases of cancer, and goes so far as to highly recommend their use in treatment. Ross[5] of Liverpool suggests that xanthine, creatine, choline, or allied products derived from dead tissue and rapidly absorbed by the surrounding cells are the stimuli to cell growth.

Calkins, Bullock, and Rohdenburg[10] have studied the "Effects of Chemicals on the Division Rate of Cells." They come to the conclusions that, "under certain conditions, some chemical products obtained by the hydrolysis of nucleoproteins have a definite stimulating effect upon the division rate of free living cells." Also, "they have evidence that the presence of cells undergoing autolysis produces the same type of epithelial reaction as that produced by pure chemical products of nucleoprotein hydrolysis." Their work certainly lends strength to the idea that cell degeneration and death may lead to increased growth of neighboring cells, even to malignancy, through the stimulating effects of chemical autolytic products.

If products of living tissues or tissue juices, and products of dead tissues have the power of greatly activating the growth of cells it certainly behooves us to study carefully the effect of each and all of the cell constituents as regards their power to activate cell growth, in order, if possible, to find the one or more specific chemical bodies that have this power.

As mentioned previously, the first bodies we think of are the inorganic salts. As is well known these act as electrolytes. Wells[11] says: "If we had no electrolytes in the cell, electric charges could not be carried about in it, and hence chemical reactions could not occur. It is this fact that makes the inorganic salts of such vital importance to the cell life." Mann is correct in saying that "ash free proteids are chemically inert, and, in the true sense of the word, dead bodies. What puts life into them is the presence of electrolytes."

We need not dwell on the importance of cell proteins. Work has already been done that demonstrates the power of products of nucleoprotein hydrolysis to stimulate the division rate of cells.

The other essential constituents of the cell, beside salts and proteins, are the lipoids or fats, possibly carbohydrates in some form, and water. The writer believes that from the standpoint of the cancer problem the study of the lipoids and the inorganic salts in relation to cell activity will offer the most interesting, if not the most valuable information.

The chief lipoid found in every cell is lecithin or a fat which is doubtless the chief carrier of phosphorus, a chemical substance absolutely necessary for growth of the nucleus. From our knowledge of bacteriology and immunity we know that lecithin has an activating power and may take the place of complement in certain immunity reactions. In his "Serum Diagnosis of Syphilis," Noguchi says: "I have found that not only samples of tissue lecithin, but also several other phosphates, as well as several acetone soluble fractions of tissue lipoids, can act as antigen." Cholesterin is another substance, found in every cell, which may have a decided influence on the rate of all growths. Abderhalden[20] thinks "it is entirely possible that lecithin acts as an accelerator in animal cells, and even on the intracellular ferments." He states that cholesterin inhibits the action of lecithin and suggests that these two important substances may have an antagonistic action in the cell. That lecithin is a metabolic stimulus is shown by Bain[17] in some recent experiments. On the other hand, Robertson and Burnett[21] find that cholesterin causes a marked acceleration in growth when injected into rat tumors, while lecithin has a retarding effect. We must take into consideration, also, the properties of *colloids,* and, perhaps of more importance still, the phenomena of *catalysis* and *enzyme* action.

In studying Carrel's work in the light of enzyme or colloid action one cannot but be impressed with the fact that there is some similarity between the action of these tissue extracts and that of enzymes. The tissue extracts have the power of greatly accelerating the reactions in connective tissue cells leading to rapid reproduction. A *concentrated* extract had much more power to activate growth than did a dilute extract. Concentration, also, has been found to increase the power of enzymes.

The actions of both the tissue extract and of enzymes are fairly specific.

These extracts and enzymes have apparently somewhat the *same "optimum temperature."* This fact also would tend to rule out the inorganic catalysis being compared to these extracts.

Filtration through a Berkefeld or a Chamberland filter greatly lowered or suppressed the activating power of the tissue extract. Enzymes, being colloids, filter poorly or not at all.

The fact also brought out that the tissue extract had much more power to activate growth when allowed to stand for some time mixed with Ringer solution, suggests the added acceleration of a coenzyme. Many of the so-called coenzymes are inorganic salts.

Inasmuch as a tumor cell differs little from a normal cell except in its metabolism and chemical activities, and inasmuch as it is difficult to understand any great difference in the forces which can cause normal cells to reproduce at forty times their normal rate, and malignant tumors, it would seem reasonable to study the origin of tumors, malignant and benign, from this same standpoint of biochemistry.

Perhaps no recent work which may throw light on the problem of cancer etiology is of so much interest and importance as that done by Rous and his co-workers[12] at the Rockefeller Institute. These investigators have experimented with chickens. One of the first findings was that they could transmit a spindle-cell sarcoma of a chicken to an apparently normal chicken by a *cell-free filtrate.* The tumor cells were macerated and suspended in a large quantity of Ringer solution and thoroughly shaken, after which the mixture was filtered. A second sarcoma developed at the site of inoculation of this filtrate. In their work they found no instance of natural infectivity or contagiousness, and cultures from the growths remained sterile as regards all known bacteria.

They believe "the action is due to a cell derangement brought about by accessory factors." In a subsequent report on "The Rôle of Injury in the

Production of a Chicken Sarcoma by a Filterable Agent" they declare that the tumor is first a minute nodule at some point in the track of the injecting needle, and they believe the "filterable agent requires for its action a cell derangement or proliferation." They found also that tumors resulted more often when a certain amount of infusorial earth was mixed with the filtrate. This action of infusorial earth (which is made up largely of inorganic chemical constituents) is interesting in view of some of our previous statements. Another important fact brought out is that when this filtrate "was injected into the bloodstream a few tumors resulted in areas of *previous focal* or *cell derangement*."

These same workers report another case in which an osteochondrosarcoma was transmitted from the original host to a second chicken by means of a filterable agent. Again the tissue was ground up, taken up in 350 c.c. of Ringer solution, sedimented, and filtered through a Berkefeld filter which will hold back the smallest of our known microorganisms. Tumors resulted in four out of six cases in the presence of infusorial earth. These generally formed by a coalescence of numerous small nodules in the track of injury of the injecting needle.

What is the thing which has this wonderful power? Does it not seem reasonable to imagine that it is either an ultramicroscopic organism, one which passes through a Berkefeld filter, or else a definite chemical substance, or group of substances which pass through in solution? To me the latter seems much more probable.

Let me now proceed to the adaptation of these theories to some of the problems of cancer.

The predisposing causes of cancer included in the "precancerous" stages have been discussed. Suffice it to say that the different causes mentioned are not only enough to cover the popular theories concerning the influence of injury and chronic irritation, but they also account for other factors such as chemical, parasitical, and functional influences which are usually unseen and unappreciated.

The common sites for the development of cancer, namely, the uterus, the stomach, the breast, the bowel, the skin, etc., are, in about the same ratio of occurrence, correspondingly liable to one or more of the primary causes of tissue degeneration, leading eventually to an attraction for the organic salts of the blood and an upset in local chemical equilibrium. The degenerated or dead cells of uterine glands, following chronic inflammation, disuse, or overactivity; the dead or dying cells in a chronic gastric ulcer; the local necrosis in a breast following an abscess; the scar tissue resulting from a past typhoid or tuberculous ulcer in the bowel or from an old *x*-ray burn of the skin, are all areas which have an affinity for inorganic salts of the circulation, and in each instance the dead cells show changed chemical reactions.

This theory in no way conflicts with the question of sex incidence in cancer, since it involves principally the *predisposing* causes or precancerous conditions, to some of which the female is more liable, and to others of which the male is liable.

Someone has said that "tumors occur in areas where physiological activity is most liable to pathological changes." It is not surprising then that the female, with her added physiological activities of uterus and breast which are so liable to pathological changes, should develop more tumors than the male.

The age incidence of cancer is too well known to need comment. Does it not correspond to the age incidence of those other conditions characterized by degeneration and upset chemical equilibrium of cells, such as the calcification of arteriosclerosis, and the deposit of other salts as in gout, etc.? In fact, is it not a common occurrence to see these different conditions existing simultaneously with cancer? On the other hand, all these conditions may exist, though rarely, in the young. Cancer frequently develops in the prematurely aged. Arteriosclerosis and calcification are closely associated with premature aging. Furthermore cancer occurs rarely not only in the very young, but also in the very old. In the majority of cases it seems to start just at the time when general body activity and vitality are at their maximum and localized aging, associated with a poor local nutrition and circulation, and an upset in the physiological equilibrium of the inorganic salts and other chemical constituents has taken place.

We are familiar also with the fact that cancer occurring in the young runs a more rapid and malignant course, while in the very old the process, when present, is usually slower. This may be explained by the influence of increased reproductive stimuli upon naturally active young cells on the one hand, and old devitalized cells on the other.

The fact that heredity plays a large part in cancer has not been definitely settled. While several cases occurring in a family may be considered mere examples of coincidence, there have certainly been instances in which cancer was so common in a family that the question of coincidence had to be dismissed. This must be explained either by assuming an hereditary transmission of the exact cause (or of a tendency of the body tissues to take on malignant growth), or by the influence of environment. All the members of one family may be subjected to a certain form of tissue injury, chronic inflammation, or irritation, due to their mode of life, their occupations, their habits, etc., or certain of their tissues may be specially susceptible to injury and degeneration. Their tissues when degenerated may show a special affinity for inorganic salts, or a special capacity for other chemical changes. We know that "hardening of the arteries," due to an affinity between degenerated vessel walls and inorganic salts of the circulation leading frequently to a definite calcification, may "run" in certain families. Inasmuch as the writer believes that cancer is due to a local disturbance in cell metabolism, it is interesting to note that those diseases which are generally classified as due to "disorders of metabolism," such as gout, diabetes, obesity, etc., are the ones most often associated with a history of heredity. We are inclined to believe that what would seem in many cases to be a direct transmission from parent to offspring is really more a question of "precancerous" environment or, at most, a transmission of "precancerous" conditions of susceptibility and metabolism such as we have suggested above.

Studying the tumors themselves, some authorities have found an increased amount of *calcium* or *potassium* present. Clowes and Frisbie,[13] studying carcinoma of mice, demonstrated a very high potassium content in rapidly growing tumors, while in slow developing tumors the calcium was considerably increased and the potassium greatly decreased. In a case of carinoma of the jaw and glands of the neck following an epithelioma of the lower lip, which I recently had the opportunity of seeing, I noticed that the blood from the raw, bleeding edge

of the tumor coagulated very rapidly. On further examination it was found that the coagulation time of the blood from this tumor was two and three-quarters minutes, while from the peripheral circulation in another locality in this same patient, at the same examination, the coagulation time was five minutes. Is this not of some significance in view of the fact that the calcium salts are supposed to play a large part in the process of coagulation? Is it not suggested that possibly the calcium salts were increased in the tumor region compared with the rest of the body? The patient, in this instance, died before the calcium content could be worked out.

How frequently we find an area or areas of calcification in carcinomatous, or, in fact, in all sorts of tumors! Is this merely a *result* of the degeneration of the tumor itself or may we find that the calcified area represents the end result of a gradually increasing local deposit of salts in dead or dying cells, which salts, previous to their insoluble condition had had an effect upon the absorptive and reproductive powers of the cells in the immediate neighborhood?

We must assume, from our studies on the regenerative powers of different cells and tissues, that each form of tissue in the body has its own characteristic normal rate of growth and reproduction, and that this rate is largely dependent upon the relative amount of nuclear substance present and the chemical constitution of the individual tissues. For example, we know that epithelium and connective tissue have normal rates of reproduction and growth more rapid and active than that of muscle, nerve, and bone. From this it appears that the rate of growth and malignancy of a tumor might depend as much on the tissue involved as upon the stimulus to increased growth. Would not this theory also serve to explain other tumors, such as teratoma and teratoblastoma originating apparently from displaced embryonic tissue, by assuming that some localized tissue degeneration due to one of many possible causes had taken place during the life of the embryo or fetus leading to a localized disturbance in chemical equilibrium and metabolism and eventually to a local increased cell growth?

Adami's statement, that the correct theory of the cause of cancer must cover *all forms* of new growths, has previously been mentioned. We would go a step further and say that such a theory should also be at least compatible with the theory of normal cell division, and the latter we believe to be due to biochemical phenomena.

The problem of metastases from malignant tumors has been of interest to clinicians and pathologists for many years. The writer believes they are formed by the transportation of cells from the original growth, and that conditions are fairly well maintained in the medium through which they are carried (either the lymph or the blood) which encourage their continued division and growth, and that such growth is aided by a lessened general or local tissue resistance on the part of the diseased person.

Furthermore, such a theory would help to explain the comparative sterility (so far as microorganisms are concerned) of tumor tissue, not secondarily infected, and also explain the lack of any evidence that contagion is possible.

Many workers have found that it is possible to inoculate tumors from one animal to another of the same species, but that such inoculation from an animal into a different species is much less successful. Further, it has been demonstrated that such tumors after transferrence continue to grow from their own cells rather than from those of the host. In other words the host apparently serves only as a satisfactory medium for the further division of the original tumor cells, rather than to have its own cells react as in ordinary bacterial infection. It thus is suggested that the blood, lymph, and tissues which are practically the same in the animals of one species so far as their biochemical properties are concerned, react with the tumor cells as well in one animal as in another, while the blood, lymph, and tissues of a different species usually exert a deleterious influence on the tumor cells because of the difference in chemical and metabolic nature.

In the light of this theory let us consider the symptoms associated with a cancer in general. Loss in weight and strength, and anemia are rather common in all progressing cases of cancer, and these are not necessarily associated with obstruction to food or failure in appetite. These symptoms may be brought about by a disorder and disproportion in metabolism in which the tumor cells are rapidly absorbing food and salts from the blood and lymph, to the detriment of the other tissues of the body which are not only becoming starved, but at the same time are unable to give off those waste products which they contain, thereby resulting in more or less *autointoxication*. A disorder in general metabolism caused by even a small tumor may be as great in degree, as the disorder in metabolism set up by such comparatively small bodies as the thyroid, parathyroid, ovary, or pituitary body when their physiological activities are disturbed.

These are all interesting problems for investigation. The writer has faith that the more the individual living cell, its molecular constitution and changes, and its surroundings are studied from the standpoint of chemistry, physics, and physiology, the closer will we approach the real truth concerning the cause of cancer and of all other cell activities, normal and abnormal.

Supposing that malignant cell proliferation is a result of the same influences which cause normal cell division, but that the former is due to a local disturbance or disproportion in these influences; knowing that certain inorganic salts are absolutely essential to normal cell activity and reproduction, and that abnormal cell division has been demonstrated as a result of a change in these salts and of the chemical medium; realizing that artificial parthenogenesis, or sexual reproduction of cells, may be brought about by chemical means, we must admit that not only normal cell division as seen in tissue growth, repair, and regeneration, but also abnormal cell division as is seen in cancer and all other new growths may be largely, if not entirely, dependent upon chemical or biochemical phenomena in the cell and its surrounding medium. Professor Richards[15] of Harvard says: "Both physiologist and pathologist in the study of the cell and its normal or abnormal growth must ultimately fall back upon chemical knowledge, because the action of the cell depends essentially upon the nature and quantity of the various chemical substances of which it is made. As the cell is the basis of all life, and as our bodies consist simply of aggregations of a great variety of cells, each of which is governed by chemical laws, chemistry must underlie all the vital functions."

*Summary.*—In this paper, after a brief review and criticism of the older theories, and a consideration of recent facts brought out in relation to the

subject, I have endeavored to suggest some new ideas as to the cause or causes of cancer, and have treated the subject from the broad standpoint of a combination of biology, chemistry, physics, physiology, bacteriology, and pathology, rather than to consider it from the standpoint of any one of these alone.

1. As a basis for the development of cancer, *primary and secondary "precancerous"* stages are discussed; the *primary* stage being local cell and tissue degeneration or necrosis due to all the known causes of such changes—a pathological problem involving mechanical, chemical, physical, parasitical, and physiological factors; the *secondary "precancerous"* stage being a local disturbance of chemical equilibrium, a chemical rearrangement, including an affinity of these degenerated areas for, and an attraction to them of, certain inorganic salts of the blood—a problem of local disordered metabolism involving physical and chemical conditions in cell and tissue.

2. It is then suggested that such a change in local chemical environment may influence the growth of neighboring cells by causing them to take on increased permeability, absorptive powers, and oxidations, and lead to accelerated activity and growth, even to malignancy.

3. Attempt is finally made to adapt these ideas to the important phenomena of cancer.

In an interesting editorial in a recent number of the *Journal of the American Medical Association*, on "Imagination in Science and Medicine," the following conclusion is reached: "The fabric of medical progress—indeed, of all progress—is woven from legitimate dreams to a greater extent than the 'practical' man is wont to realize or willing to admit."

It is the hope of the writer that what may seem impracticable in the above ideas may at least be looked upon as a "legitimate dream," and may stimulate further work in this interesting, though so far neglected, field of cancer research.

## RESULTS OF OPERATION FOR GASTRIC ULCER.*

### A PLEA FOR RADICAL OPERATION WHEN OPERATION IS INDICATED.

By ALBERT F. R. ANDRESEN, M.D.,

BROOKLYN, NEW YORK.

GASTROENTEROLOGIST, BUSHWICK HOSPITAL, POLHEMUS MEMORIAL CLINIC, AND BROOKLYN HOSPITAL DISPENSARY.

The discussion of the etiology, diagnosis and treatment of gastric ulcer has in recent years occupied a most prominent place in medical literature. The etiology is still obscure, although many facts now point to a bacterial invasion of the gastric mucosa as the cause of the ulceration. Mistakes in diagnosis still occur but are becoming daily less frequent. It is in regard to treatment, both medical and surgical, however, that the greatest diversity of opinion has occurred. The internists have too often felt that medical treatment was all that was required in all cases, and the surgeons have declared that operation was the only cure. In the past year, however, we find a greater unanimity of opinion prevailing, especially among those considered authorities in this field. Carefully compiled statistics have shown that from 60 to 90 per cent. of simple acute ulcers, and 50 per cent. of chronic ulcers are cured by proper and prolonged medical treatment. Mallory[16] has estimated the average mortality from medical treatment alone to be but 5 per cent., with pyloric stenosis occurring in 10 per cent. of cases, and carcinoma in 3 per cent. Many ulcers have without doubt been operated upon where operation was not indicated, and poor results have been obtained as a consequence.

The *indications for operation in gastric ulcer*, as now generally accepted by all authorities, are as follows: (1) In uncomplicated ulcer the only cases calling for operation are those in which the pain and distress are not relieved by prolonged and adequate medical treatment, and those chronic ulcers in which, in spite of careful treatment, frequent exacerbations occur. (2) The complications of gastric ulcer calling for operative interference are: (a) profuse hemorrhages which recur and threaten the life of the patient; (b) perforation, acute or chronic; (c) severe disturbances of gastric motility, as in pyloric stenosis or hour-glass stomach, whether caused by internal cicatrices or external adhesions (perigastritis). While these indications for operation are now generally recognized, we still find considerable diversity of opinion among surgeons regarding the proper operative procedure to be employed. Formerly gastroenterostomy was considered to be the ideal operation for ulcer, except occasionally in cases of hemorrhage or perforation, when the opening or bleeding point was sutured. The operation of gastroenterostomy was, therefore, perfected, and posterior gastrojejunostomy as practised today is not only a safe but a simple procedure. It was found, however, that symptoms were not permanently and often not even temporarily relieved by this operation, especially in uncomplicated cases where the ulcer was not at or

*Read before the Brooklyn Society of Internal Medicine, February, 1912.

near the pylorus. Excision of the ulcer seemed, therefore, a more rational procedure, and this was done, with the result that these stomachs frequently developed constrictions at the site of operation, resulting in hour-glass stomach and requiring subsequent gastroenterostomy. It was then that the modern, rational operation of excision of the ulcer with gastroenterostomy was generally adopted in these cases. But even in ulcer at or near the pylorus it has been shown, in a large number of cases, that gastroenterostomy alone is not curative. The relief from ulcer symptoms experienced after gastroenterostomy is now pretty generally held to be due, not to drainage, as was formerly held to be the case, but to the neutralizing of the hyperacid gastric juice by regurgitation of the alkaline intestinal juices into the stomach. This improvement, as Schur,[1] Fink,[2] and others have shown, results in the relaxation of the pyloric spasm and in decrease in size of the ulcer, both of which conditions favor the passage of food through the pylorus, and gradual closing of the gastroenterostomy opening. Conditions then are as they were in the beginning, and recurrence of all symptoms may be expected and often does occur from a few months to several years after the operation. We are told that careful postoperative treatment for many months or years is necessary to obtain the best results, and we are inclined to wonder whether many cases would not have done as well without gastroenterostomy.

On considering the facts stated above, we should conclude that, theoretically at least, excision of a gastric ulcer combined with a posterior gastrojejunostomy is the most desirable operation. I hope in this paper to prove its practical value without a doubt.

Although I have but ten cases to report, I think that a careful study of these cases will convince us of the advisability of doing radical work where operation is indicated. Of fifty-two cases of gastric ulcer seen at the Polhemus Clinic in the past year, we had an opportunity of seeing the results of operation in ten cases, reports of which are given at the end of this article. Five were seen by us before operation and referred to the surgeons, and five came to us after operation had been performed, of which number three required further operation. In addition to this, three patients on whom we considered operation advisable were lost to our notice. Thirteen operative cases out of fifty-two observed —an operative percentage of twenty-five—would seem to indicate an excessive desire on our part for operation in gastric ulcer. It is explained, however, by the fact that we probably see more advanced and complicated cases than the average observers, the cases reported having all been operated upon for complications.

Of our ten cases, nine were males. Two were under thirty years of age, five over 40 years. Of the seven plyoric ulcers (Cases I, II, III, V, VII, IX, and X) five had a simple gastrojejunostomy performed, of which three, or 60 per cent., had a recurrence of ulcer symptoms. One was simply resected and a recurrence required subsequent gastroenterostomy, which resulted in cure. One case was not properly operated upon because not recognized at operation. An ulcer of the greater curvature (Case IV) was apparently cured by gastroenterostomy alone, while one of lesser curvature (Case VI), with the same operation, had a recurrence. Excision of an ulcer of the posterior wall by the transgastric method, without gastroenterostomy (Case VIII), resulted in an hour-glass stomach, which was subsequently cured by gastroenterostomy.

It will be seen that while the surgeons operating upon this series of cases rank among the best in Greater New York, not one of these cases had an operation for excision combined with gastroenterostomy. Of the ten cases only three, or 30 per cent., were apparently cured by the first operation, while two more were cured at subsequent operations which completed the combination of gastroenterostomy and excision. An analysis of these ten cases, which distinctly indicates the necessity for this combined operation in all cases of gastric ulcer requiring operation, only serves to corroborate the testimony of many other observers. Zweig[3] reports twelve gastroenterostomies with only five good results; Albrecht,[4] forty cases operated upon by Brunner with 62 per cent. cured; Herrick,[5] six cases with three cured; Schmitt,[6] sixty-two cases with 51.6 per cent. cured, and Härtel,[7] twenty-two of Bier's cases with sixteen cures. These, with our own cases, give us reports of 149 cases, with an average of 56.3 per cent. cured—a pretty poor showing, considering the risks of operation.

Results from excision combined with gastroenterostomy are far more encouraging. The Mayos[8] report a large percentage of cures; Lockwood[9] places the percentage of cures at eighty-five; Coffey[10] reports five cases, all cured; Herrick,[5] two cases cured. Our own two cases (VII and VIII), in which this operation was finally completed at secondary operations, were both cured. Unfortunately, other writers, Kuttner,[19] Pilcher,[11] Fowler,[12] and others, do not mention the percentage of cures, but all speak of the necessity for excision. Ulcers of the posterior wall are removed by the transgastric method, first suggested by L. S. Pilcher in 1908.[11]

While it is thus seen that, from the standpoint of percentage of permanent cures obtained, excision of an ulcer with gastroenterostomy is the ideal operation, the mortality from this operation must be compared to that of the less radical procedures. It is on the strength of this that so many surgeons still decline to do the radical operation. Herrick places the mortality for gastroenterostomy at 1 to 2 per cent., for excision at 5 to 8 per cent.; Lockwood, for gastroenterostomy in skilled hands at 2 per cent., in hands of the average surgeon, at 6 to 8 per cent., and for excision at 10 to 15 per cent. The operative mortality of the Mayos,[8] in 1,000 operations for gastric and duodenal ulcer, in most of which excision was done, is 2.4 per cent., while a number of surgeons report small series of cases with no deaths. We may conclude, however, that the immediate mortality is probably from 2 to 5 per cent. higher where excision is done. This is the immediate operative mortality. But now let us consider the ultimate mortality. We have shown that 40 per cent. of the cases on which the less radical operations are done have recurrences, and either undergo future operations, with their attendant mortality rate, or are allowed to go on to serious complications. And not only this, but probably 10 per cent. of cases after simple operation develop carcinoma. Wilson and McCarty,[13] working in the Mayos' clinic, have informed us that from 70 to 78 per cent. of their cases of gastric carcinoma showed undoubted evidence of having developed on an ulcer base, and Payr has stated that 26 per

cent. of all ulcers become carcinomatous. Kuttner[13] found cancer in fourteen out of thirty cases in which he resected what he thought was a callous ulcer, and Rowlands[14] reports a similar experience in two cases. After gastroenterostomy, subsequent development of carcinoma on the ulcer base is apparently not prevented, Albrecht[4] reporting it in 10 per cent. of cases operated upon by Brunner, Herrick[5] in two out of six cases. It has not been determined whether carcinoma ever develops in the scar resulting from excision of an ulcer, but the chances of this occurring are manifestly less in the fine, thin scar left after excision than in the tough cicatrix left even when the ulcer heals. The Mayos[8, 17] do an excision of an ulcer combined with gastroenterostomy wherever possible, and have positively stated that gastroenterostomy alone is never a cure, but only a palliative measure. All authorities agree that the best results cannot be obtained without careful ulcer treatment for months after operation. Failure to do this often results in a recurrence of the ulcer symptoms, and jejunal ulcers have been shown to result from neglect of this precaution.[18]

*Conclusions.*—(1) Patients with simple uncomplicated gastric ulcer should not be subjected to operation, as has been so frequently done in the past, but only in the presence of one of the definite indications mentioned above should operation be advised. (2) In cases of gastric ulcer requiring operation, not only theoretically, but practically, both from the standpoint of permanency of cure and of mortality after operation, excision of the ulcer, combined with gastroenterostomy, is the operation of choice, and should be performed wherever the condition of the patient will permit. (3) When the patient's condition is not good, and operation is imperative, a palliative operation should be performed, with the understanding that subsequent operation may be required. (4) Thorough postoperative treatment, often neglected, should be insisted upon in all cases, and should be entrusted only to those specially qualified in this field. The surgeon should not consider that his duty is ended until the patient is in the hands of a competent internist.

*Case Reports.*—Case I: Mr. J. T., Norwegian, aged fifty-six years, a ship's cook, first applied at clinic in August, 1911. Family history negative. Had been in good health until a few months before, when he had spent a few months at the Long Island College Hospital under treatment for abdominal pain and vomiting. Treatment had consisted of rest, soft diet and lavage, and had caused relief until one week before he applied to clinic. Since then he had had severe pain in epigastrium immediately after eating, always relieved by vomiting, and following any kind of food. Bowels had always been constipated. There was not much loss of weight. Examination disclosed an anemic, somewhat emaciated man; chest negative; abdomen soft, epigastrium tender, splash to umbilicus. Removal of gastric contents 16 hours after a rice and raisin meal produced 275 c.c. of fluid contents, containing gross rice and raisins, with free HCl 42, total acidity 65, no occult blood. Stool negative. Diagnosis, chronic ulcer obstructing pylorus. Operation at the Long Island College Hospital disclosed a chronic ulcer, the size of a walnut, at the pylorus, on its lower and posterior surface, the pyloric opening being a mere dimple. A posterior gastrojejunostomy was done, and patient left the hospital 16 days later. He went back to work and felt well for 3 months, when he began to feel occasional sticking pains in the upper abdomen, with occasional cramps, and a return of his constipation. This is evidently a case of recurrence of the ulcer. He has since been lost sight of.

Case II.—Mrs. A. S., American, aged thirty-four years, applied at clinic in February, 1911. Family history negative. Had always been healthy, and had four healthy children. For four months patient had had persistent pain in the epigastric region, made worse by eating (immediately), and accompanied by belching, pyrosis, nausea, occasional coffee-ground vomiting and occasional tarry stools. The bowels were regular. Loss of 25 pounds in weight in 4 months. Examination: Chest negative. Abdomen very fat and flabby; visceroptosis; tenderness in left epigastric region; apparent thickening at lower border of stomach. Gastric contents removed 4 hours after Ewald test meal showed 30 c.c. of contents, free HCl 86, total acid 90. Stool contained occult blood. Diagnosis, gastric ulcer. Treatment: The usual dietetic and medicinal measures gave relief for a time, but the patient had frequent exacerbations of the pain and vomiting, which so distressed and weakened her that operation was advised, and she was operated upon in the Long Island College Hospital on November 10, 1911. The stomach was found to be large, the gall bladder adherent to the duodenum 4 inches from the pylorus, and a chronic ulcer, the size of a lemon, surrounded by dense adhesions, and giving evidences of a previous rupture, was found at this point, partially occluding the lumen of the gut. A posterior gastrojejunostomy was performed, and a long appendix removed. The patient made a good recovery, leaving the hospital in two weeks. She has been doing very well since, having had no recurrence of symptoms. She is still receiving ulcer treatment.

Case III.—Mr. E. K., American, aged twenty-five years, a property boy in a theater, applied to us in July, 1911. Family history negative. He had no bad habits, and had never been ill until 10 months before, since which time he had had abdominal pains coming on 15 minutes after eating, and lasting ½ to 1 hour. He had never vomited, had had morning diarrhea for about one-half the time, and complained of anorexia and dizziness. Four months before he had been operated upon at the Flower Hospital, New York City, where a pyloric stenosis was diagnosed, and a gastroenterostomy done. He showed no improvement after the operation. His stools were frequently tarry, both before and after the operation. Examination: Chest negative. Abdomen was tender in epigastric region, a little to left of median line, and a clean epigastric scar was present. This patient did not return for further examination, but his was evidently a case of recurrence of an ulcer after gastroenterostomy.

Case IV.—Mr. A. A., Norwegian, aged thirty years, single, and a waiter by occupation, came to the clinic in September, 1910. Family history negative. He had been healthy all his life except for a gonorrheal infection which was speedily cured. Had formerly drunk considerable alcohol. For two years he had had epigastric pain coming on 2 hours after eating, relieved by food, and accompanied by pyrosis, anorexia, occasional vomiting and constipation. He had once vomited blood, 2

years before. He improved somewhat on the usual ulcer treatment, but in November had a profuse hemorrhage and demanded operation. At the operation in the Long Island College Hospital an ulcer of the greater curvature was found, a gastrojejunostomy was done, and patient made an uneventful recovery. At the end of a year he is still without a recurrence of his ulcer symptoms.

Case V.—Mr. J. T., American, aged twenty-seven years, married, piano polisher, was first seen at the clinic in January, 1911. Family history negative. He had never been ill till 2 years before, when he began to have epigastric pain 2 to 3 hours after eating, radiating to right side of chest and to back of shoulder. His bowels had always been regular. He said that 2 years before he had passed some gall stones. On applying at clinic he said he had been jaundiced for 2 weeks. At operation in the Long Island College Hospital the gall bladder was found to be normal, but an ulcer was found at the pylorus, not totally obstructing it. A gastroenterostomy was done, and one year later the patient is still free from ulcer symptoms.

Case VI.—Mr. L. F., Russian, aged forty-eight years, applied at the clinic in July, 1911. Family history negative. He was well until ten years before, when he began to have typical ulcer symptoms, for which he received treatment at irregular times until operated upon at the Jewish Hospital in February, 1911. An ulcer of the lesser curvature was found and excised. For 4 weeks he felt better, when his symptoms returned. He had epigastric pain 2 hours after eating, and relieved by food He had also continuous lower dorsal pain. Examination elicited considerable tenderness in mid-epigastrium. One hour after an Ewald test meal 200 c.c. of gastric contents were obtained, with free HCl 28, total acidity 52. This case has improved considerably under medical treatment, but it is safe to say that result of operation would have been better if a gastroenterostomy had been combined with the excision.

Case VII.—Mr. E. M., American, aged forty-three years, gardener, first applied at the clinic in July, 1911. Family history, father died of gastric carcinoma. Patient had formerly been a heavy drinker, but was always healthy. Two years before, after ulcer symptoms for 3 years, succeeded by persistent vomiting, patient had been operated upon at the Long Island College Hospital, resection of a pyloric ulcer being done. He had been doing very well except for occasional "stitches" in the scar, until 5 months before, since which time he had been troubled with constipation and occasional vomiting. For 2 weeks he had been vomiting everything 2 hours after eating. He had a good appetite, but was afraid to eat. He had lost 37 pounds in 5 months, and felt dizzy and weak. Examination disclosed an anemic, emaciated man, with normal chest findings. He had a large ventral hernia through the scar of his operation, which was not tender. He was somewhat tender to the right of the umbilicus. The superficial abdominal veins were prominent. The gastric contents, removed 1 hour after an Ewald test meal, consisted of 20 c.c. of poorly chymified, bile-stained material, with an absence of free HCl and total acidity of 25. No blood was present. Stool was negative. Urine negative. Medical treatment not resulting in much relief, patient was referred back to the surgeons in August, when a gastroenterostomy was done. No ulcer symptoms have occurred since. Constipation persists.

Case VIII.—Mr. T. C., American, aged forty-three years, married, laborer, was first seen in July, 1911. Family history negative. Periodic heavy drinker, with a dry cough for many years. For 4 months he had had epigastric pain every day, and was finally operated upon at the Long Island College Hospital 7 months before he applied at the clinic. A transgastric excision of an ulcer of the posterior wall of the stomach was done at that time, but gastroenterostomy was omitted because of patient's poor condition, although plainly indicated because of the constriction caused by the removal of the ulcer. After the operation he vomited constantly for awhile, but finally improved somewhat and was permitted to go home. On applying to us he had severe pain in the epigastrium 1 to 2 hours after eating, relieved by food, and occasionally relieved by vomiting. Examination revealed a tuberculous lesion of the right apex, and an enlarged liver. Some tenderness on deep pressure over the epigastric scar. Rice and raisin meal was obtained 16 hours after eating, indicating serious obstruction, and patient was referred back to the surgeons, who found an hour-glass stomach, and did a gastroenterostomy. No further gastric distress has occurred since, but the exaggeration of his pulmonary condition has made the patient an invalid.

Case IX.—Mr. I. F., Russian, aged thirty-five years, married, cutter, first applied at the clinic in April, 1911. Family history negative. For 13 years the patient had had typical ulcer symptoms—burning epigastric pain, relieved by left-sided position, and occurring 2 to 3 hours after eating, pyrosis, occasional vomiting, fear of food, constipation and tarry stools. In November, 1910, he had been operated upon at the Beth Israel Hospital, New York City. No ulcer was found, but some adhesions about the pylorus were removed. No improvement resulting, the abdomen was again opened 8 weeks later and the appendix removed. No relief whatever resulted. All symptoms experienced before operation persisted thereafter. Examination showed the chest negative, abdomen very tender in mid-epigastrium. There was a large scar, showing evidences of infection. Gastric contents removed 1 hour after an Ewald test meal showed 200 c.c. of well-chymified material, forming three definite layers on standing, free HCl 28, total acidity 58. This patient was not seen again until recently, when he still showed undoubted evidences of an ulcer at the pylorus. This is one of the cases in which, as occasionally occurs, an ulcer was not recognized at the operation. He will require operation later.

Case X.—Mr. J. W., Russian, aged thirty-eight years, married, tailor, was first seen at the clinic in September, 1910. Family history negative. Previous history: Eleven years before he had had an abscess of the left thigh with septicemia. Venery denied. Twenty years before he had had an attack of vomiting, which had continued at intervals for 2½ years. This had been finally stopped by medical treatment, and patient had been well till 10 years before applying to us. Then he had begun to have burning, tearing epigastric pain, coming on 1 to 3 hours after eating, running through to back, and relieved by food. Patient said he could not lie on back unless stomach was full. He had consid-

erable pain at night, relieved by food. He suffered from pyrosis, but had not vomited. Constipation was present; color of stools never noticed. Examination disclosed an anemic, under-nourished man, chest negative, abdominal wall poorly developed, splash to umbilicus. Tenderness to right and above umbilicus. No dorsal tenderness. Right inguinal hernia. Gastric contents, 1 hour after Ewald test meal, showed a good chymification, free HCl 40, total acidity 90. Stool negative. The usual medical and dietetic treatment giving no relief, patient was referred to surgeons in January, 1911. Operation at Gouverneur Hospital, New York City, disclosed an ulcer near the pylorus. A gastro-enterostomy was performed, but ulcer was not excised. The appendix was removed and the hernia closed. Patient returned to clinic shortly after operation, and then had considerable pain and gas, which were relieved by one month's medical treatment. He then was well except for occasional constipation until October, 1911, when all the former ulcer symptoms returned, and patient for first time noticed tarry stools after severe attacks of pain. He also had a very severe headache. Medical treatment since then has given but slight relief, and patient is to be reoperated upon as soon as his affairs permit. His latest examination of gastric contents shows presence of much free bile, indicating patency of the gastroenterostomy opening. The free HCl is 22, total acidity 36. Stool negative for occult blood.

## THE PASSING OF PARASYPHILIS.

By S. POLLITZER, M.D.,

NEW YORK.

Noguchi's discovery of spirochetes in the brain in paresis closes a most interesting chapter in the history of syphilis. It was not long after the recognition of tabes as a clinical entity, mainly through the labors of Romberg, Duchenne, and Wunderlich, sixty years ago, that the frequent association of this disease with a history of syphilis was noted. But it was not till the publication of Fournier's statistics at the end of the seventies that the question of the syphilitic origin of tabes was seriously discussed. Since that time to the present day neuropathologists have been divided into two camps, one side led mainly by Fournier and Erb, who insisted that tabes was caused by syphilis, the other represented by Charcot, Westphal, and Leyden, who denied to syphilis a pre-eminent rôle in the etiology of the spinal disease.

In 1880, Mendel's monograph on the relations of progressive paralysis to syphilis appeared, and the story of the controversy that had raged over tabes was repeated in regard to paresis. In both these diseases there was on the one hand the overwhelming evidence of an intimate connection with syphilis, based on statistics covering thousands of cases, and on the other, the absence of direct proof in the nature of the anatomical lesions and even of the indirect proof which might have been based on a successful antisyphilitic therapy.

It was as a compromise between the two camps that the idea was brought forward that tabes and paresis were postsyphilitic or parasyphilitic diseases, not directly caused by the germs of syphilis, but, in the terms of the growing science of bacteriology in which pathologists were beginning to think, produced by a specific action of the toxins of the problematic organism of syphilis on certain portions of the brain and cord. This view met with considerable favor, and when the number of cases, especially of tabes, that were arrested in their course by energetic specific treatment, increased, when Erb and Nonne showed that tabetic cords sometimes disclosed small foci of distinctly syphilitic character, and when the results of the Wassermann test in these diseases of the central nervous system added force to the previous statistical evidence, the opposition to the views of Fournier and Erb seemed to weaken.

At one stroke the discovery of spirochetes in the brain of paretics has cleared away the dust of forty years of controversy. Paresis is not an indirect effect of syphilis, but is a disseminated spirillosis of the brain, is syphilis itself.

In specimens from some 200 cases of paresis, many of them poorly stained sections only, Noguchi has found spirochetes in forty-eight cases—approximately twenty-five per cent. This percentage, it is safe to predict, will be enormously increased when the technique of the staining methods is improved, and sufficient time for more thorough examinations of the affected brains has elapsed.

It is interesting to note that Noguchi's positive spirochete findings in the great majority of cases were made in comparatively rapid cases of paresis; that is, in those of short duration. If further studies show that the spirochetes are few or absent from the brain in prolonged cases of paresis, we shall have a further corroboration of the view that the nervous system is not a favorable soil for bacterial growth, that organisms which invade nerve tissue do not thrive there, and, however much damage they may do, soon die out. This is certainly the case with leprosy of the nerves in which, it will be recalled, for a long time after the discovery of the *Bacillus leprœ*, no organisms could be detected; and it was only when freshly invaded nerve stems were excised and examined that the bacilli were demonstrated. Neuritis leprosa was shown to be an effect, not of toxins, but of the direct invasion of bacilli which soon disappeared, leaving behind them

interstitial and parenchymatous degenerations which persisted, progressing till the greater portion of the nerve was destroyed.

Analogies often lead to false conclusions, but the suggestion lies close at hand that in tabes, as in paresis, the discovery of spirochetes will soon be announced, and it will be in cases of short duration, cases in which an intercurrent affection has brought the patient to autopsy early in the course of his tabes, that the organisms will be found in the cord. The common reaction of the tissues to the presence of spirochetes is the formation of connective tissue. In the skin or in the liver a scar causes no great injury to the organism. But in the central nervous system, even a small area of scar tissue produces irreparable damage, direct and progressive. The destruction of a few ganglion cells in the spinal nerve ganglia or their homologues, the Gasserian and jugular ganglia, through the direct action of spirochetes, will satisfactorily account for most of the phenomena of tabes.

The wide interest which the recent striking advances in our knowledge of syphilis—spirochetes, the Wassermann reaction, salvarsan—have stimulated, has brought about a more general understanding of the pathology of the disease. Among many new things, it has been brought home to us that the spirochetes within a few weeks of their inoculation invade every tissue of the body and, not least, the central nervous system. If they are not destroyed there by the natural agencies of defense or by treatment, irreparable injury results. The lesson is obvious; every case of syphilis should receive the most energetic treatment as soon after infection as the diagnosis can be made. The old teaching that treatment should await the development of secondary symptoms is absolutely to be condemned. It means that we should wait till the system is flooded with spirochetes! The diagnosis must be made by means of the demonstration of spirochetes in the initial lesion and the treatment by excision or destruction of the chancre and repeated doses of salvarsan followed by an energetic course of mercury instituted at once. Only thus can we hope to prevent the severe lesions of the later period of syphilis, the most terrible of which are those spirilloses of the central nervous system which we have heretofore known as parasyphilitic.

## THE SIGNIFICANCE AND MANAGEMENT OF HYPERTENSION.

By HENRY FARNUM STOLL, M.D.,

HARTFORD, CONN.

ASSISTANT PHYSICIAN TO THE HARTFORD HOSPITAL.

The study of the pulse is as old as medicine, and the ominous import when it is hard and non-compressible has long been recognized. The perfection of instruments for accurately determining the blood pressure was a great stimulus to the study of hypertension. While the clinician of large experience can estimate the blood pressure by digital means with considerable accuracy, it is nevertheless universally acknowledged that much more reliable results are obtained when a sphygmomanometer is used. A number of instruments have been devised, and while differing as to the method of recording the results, all the reliable ones are equipped with an arm piece 12 cm. wide, as with a narrower cuff too high readings are obtained in those with large arms.

The factors determining the blood pressure are the energy of the heart, the peripheral resistance, the elasticity of the arterial wall, and the total volume of blood, the first two being of the most importance.

To overcome the normal vasomotor tone a certain degree of pressure is necessary. This has been spoken of as an "essential pressure" and is stated by Janeway[1] to be about 50 mm. of mercury. In addition to the so-called "essential pressure," there is a pressure of from 70 to 90 mm. over and above this, which is dependent upon the various mental, physical, and physiological activities, which may be termed the "incidental or functional" pressure.

The normal systolic pressure for men during early life is about 140, and for women of a corresponding age between 100 and 130. The diastolic pressure is from 20 to 40 mm. lower than this. The difference between the systolic and diastolic pressure is spoken of as the pulse pressure.

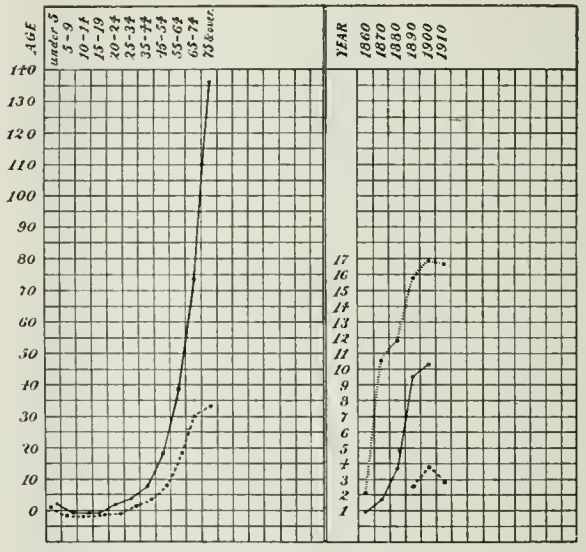

Fig. 1.—Deaths from Bright's disease (males) according to age, per million living. Continuous line, U. S.; broken line, England and Wales.

Fig. 2—Mortality from kidney disease per 10,000 living, from 1860 to 1910. New England, continuous line; New York City (Manhattan and the Bronx), cross-marked line; England and Wales, broken line.

As the peripheral resistance is increased, it is obviously necessary that the essential pressure be raised; a fact that must be fully appreciated in our efforts to reduce blood pressure. That a certain degree of hypertension is required by individuals with sclerotic kidneys is apparent upon witnessing the somewhat alarming symptoms resulting from the too liberal use of vasodilators. But we are still in ignorance as to why this is so. The theory that more blood is sent through the kidney when the pressure is raised is not borne out by animal experimentation, and it has also been shown, both experimentally and clinically, that hypertension does not increase the amount of urine. Lawrence[2] determined that an increase of pulse pressure—that is, an increase of the caliber of the vessel—had a diuretic effect, especially when it was due to a fall in both systolic and diastolic pressures. Reduction of the kidney substance beyond a certain limit results in hypertension, though how this is brought about is unknown.

One of the functions of epinephrin, the hormone secreted by the suprarenal glands, is to constrict the

muscular coats of the blood vessels. By stimulation of the splanchnic nerves after all the viscera save the adrenals had been removed, Asher[3] was able to obtain a rise of blood pressure, and of especial significance it seems was the fact that a prolonged stimulation was followed by a continuous and prolonged hypertension. Cannon[4] has also demonstrated that strong passions increase the output of epinephrin with an accompanying rise of pressure. It has long been known that strong emotion, notably anger, would sometimes induce an attack of angina pectoris in those affected with this malady, and it is related that John Hunter once remarked, in speaking of his attacks, that "his life was in the hands of any rascal who chose to annoy and tease him." He spoke truly as he died in an attack induced by a fit of anger. Thus far it has never been shown that there is an increased production of epinephrin in nephritis, but there is considerable to suggest this possibility.

The contention of Hasenfeld[5] and Hirsch[6] that hypertension without sclerosis of the peripheral arteries or kidney lesion was due to arteriosclerosis of the splanchnics, has been disproven by the experimental work of Longcope and McClintock[7]. These two observers also found that 83 per cent. of individuals presenting an hypertrophied heart and sclerosis of the abdominal aorta with narrowing of the splanchnics also had chronic nephritis. Lee[8] found a kidney lesion in 71 per cent. of fifty-three individuals subjected to an autopsy, who had had a blood pressure of over 160. In 15 per cent. of his cases a cerebral lesion was the cause of the hypertension. Only once did he find arteriosclerosis without kidney, cerebral, or cardiac lesion, other than simple hypertrophy and dilatation. He states that Sawada had never seen a tension over 170 in simple arteriosclerosis. Most interesting in this connection are the findings of Elliot and Arnott Dickson.[9] They examined 500 miners, none of whom had symptoms referring to the circulatory system. Of this number 456 had definite arterial thickening. In many instances the artery could be picked up between the fingers. Out of 116 men under twenty years of age, 100 had easily palpable arteries; yet in only 6 per cent. was the pressure 140 or over. It is evident that "arteriosclerosis is a structural change, and that hypertension is a functional derangement" which, when long continued, may result in arterial degeneration. Huchard refers to the cases of hypertension without obvious cause as being in the "presclerotic stage." In a recent series of 100 cases recently reported by Janeway[10] nephritis was the clinical diagnosis in 79 per cent.

The increase in the mortality from kidney disease in this country has been so marked during the past fifty years that it is deserving of serious thought. In the New England states it is ten times higher than at the beginning of the Civil War, and though the increase has been universal throughout the country, it is quite significant that the highest mortality is reached in New York, where "step lively" is the password. In England, where life is more tranquil, the death rate from Bright's disease has varied but little during the past decade, and is about one-third what it is in this country. The increase which begins in the teens, becomes very apparent during the twenties, and from then on jumps upward in leaps and bounds as is shown in the chart[11].

While the taking of the blood pressure should be the routine in the examination of all individuals past middle life, there are a few symptoms that especially call for the use of the sphygmomanometer. These are vertigo, sleeplessness, headache, flatulency, polyuria, dyspnea on exertion, nervousness and irritability. Flatulency in the sedentary adult should always suggest the heart as the cause, even as we look to the stomach to explain the heart pain of those in early life. Extreme nervousness is not infrequently the most marked symptom, and when it occurs in a woman we are too prone to attribute it to "the change of life," or to neurasthenia. Drowsiness and slight forgetfulness may be present and sometimes a fulness in one or both sides of the head is complained of. Janeway[10] found that visual disturbances, polyuria and headache increased the gravity of the prognosis as foreshadowing the onset of uremia, but that anginal attacks did not make the prognosis any more unfavorable. The classification of Janeway's 100 cases as to the cause of death is very interesting and somewhat of a surprise. In only 14 per cent. was cerebral apoplexy the cause, while heart failure claimed 29 per cent. and uremia 35 per cent.

One estimation of the blood pressure should never be taken as final. The public has heard just enough about blood pressure to be easily alarmed, and a slight hypertension may be wholly due to nervousness. It is moreover unwise for the patient to know the exact manometer reading, as it is almost sure to result in unnecessary worry.

*Management.*—If detected early, when the pressure is but moderately raised, we can oftentimes avert serious consequences by proper management. To this end we must search diligently for the cause. It may be overeating, business worry, or too many strong cigars. A stained blood smear may give the clue, by showing the characteristic stippling of lead poisoning. In other cases we can find no cause either in the history, the physical examination, or in the urine. But the term "idiopathic" should not be employed until the phenolphthalein kidney function test has been used. With hypertension there will frequently be found a distinct diminution in the amount of dye eliminated, and this is usually more marked in the first hour than during the second after the first appearance of the color. Not only may the elimination in the second hour be normal, but in one of my cases 30 per cent. was eliminated during the second hour and only 13 per cent. in the first. The patient died soon afterward of chronic uremia. It appears that this test gives a better indication of the kidneys' ability to eliminate the toxic substances which cause the symptoms in nephritis, than does any examination of the urine.

The dangers of long-continued high blood pressure are two-fold. The arteries becoming sclerosed may rupture, or the heat may succumb. Except for the cases where the low blood pressure is dependent upon weak heart action, the prognosis becomes progressively worse as the pressure rises. Fisher,[12] studying the mortality rate in over two thousand policyholders, with a blood pressure between 140 and 149, found it to be slightly below the normal death rate of the company at the end of two years. Five hundred and twenty-five persons insured with a pressure of 150 or over, the mortality was 35 per cent. in excess of the average, while 722 persons declined, whose pressure was 170 or over, the death rate was four times greater than that of the general aver-

age of the company. While most of us have followed cases for ten years or more with a pressure of 200, in general the duration of life is about half that time.

Every case presents three problems: Shall the patient exercise, or does he need rest in bed? What shall be his food, and what drugs, if any, are indicated?

Upon the detection of any considerable degree of hypertension, it is desirable to have the patient go to bed for a period of observation. This is particularly indicated with the very nervous. With a good heart muscle, nothing seems to be gained by keeping the patient in bed more than a few weeks.

Rest in bed becomes imperative, however, when cardiac failure threatens. A diagnosis of myocardial insufficiency is usually made with much hesitancy when the examination of the heart is negative, but the symptom that should put us on our guard is breathlessness either on slight exertion or paroxysmal in type. Janeway[10] found that cardiac failure was the cause of death in 50 per cent. of the patients in whom this was the most prominent symptom, and that 24 out of 29 who died of cardiac failure, had dyspnea as an early symptom. To await the engorgement of the liver or the development of the edema before instituting treatment to sustain the heart is like refraining from rescuing a shipwrecked man because he still has a piece of wreckage to hold to. We may detect a reduplication of the second sound or the sounds may be normal. Green[13] thinks a splitting of the second sound, heard to the left of the sternum in the third interspace, is the earliest auscultatory evidence of myocardial failure.

Disregarding the blood pressure, these patients are to be treated as cardiac cases. When the heart gives signs of regaining its tone, it is important that graduated exercise be instituted to perfect the compensation, but Nauheim baths are not to be commended.

It has been shown that blood pressure drops during sleep, especially during the first part. I have several times noted a considerable fall following a half hour's sleep in a patient with hypertension. For this reason I think it is very desirable that all such cases should rest and preferably sleep for half an hour after the midday meal. Other things being equal, it seems that the prognosis is better when a considerable drop in the pressure follows a short nap or a small dose of a vasodilator, providing this is not accompanied, in the latter case, by any unpleasant symptoms. This is not an absolute rule, however, as I have had a patient under observation for ten years whose symptoms have changed but little and whose pressure of 200 persists in spite of everything. It is worthy of note that this patient recently showed excellent kidney function with the phenolphthalein test, eliminating 62 per cent. in two hours and 53 per cent. in the first hour alone.

The importance of the regulation of the diet and the habits of the patient can scarcely be overestimated, for it is by this means we can lessen, to a considerable degree, the functional or incidental element in the blood pressure. This is particularly true when there is a strong family history of arterial disease. In the first place, the total volume of food should not be excessive, as it is not at all uncommon for these individuals to suddenly die shortly after eating a hearty meal. The drinking of much liquid with meals is to be discouraged, as it tends to increase the amount of food consumed. Exercise directly after a meal should always be interdicted because of the increase of pressure thus occasioned.

Protein food should be eaten sparingly, a small amount of meat or fish once a day being permissible as a rule. But the symptoms of chronic uremia are sufficient grounds for eliminating it from the diet for a time at least. Salt should be used in moderation, except when edema is present, when its use should be greatly restricted. Meat extractives should be interdicted and the dietary should be made up largely of cereals, milk, vegetables, and fruits.

A daily warm bath is desirable, but the cold bath is inadvisable, as it raises the blood pressure. Tobacco and coffee should be greatly restricted and preferably forbidden, while business cares should be reduced to a minimum. There should be a daily evacuation of the bowels, a daily small dose of salts being very satisfactory if costiveness is present. A brisk purge is one of the best means of controlling high pressure and it may be given two or three times a week. Excessive purging is to be guarded against, as it sometimes occasions considerable prostration due to too great lowering of pressure.

The development of any acute infection—bronchitis, tonsillitis, or even a "common cold"—in a patient with high blood pressure cannot be considered a trivial affair, for an acute nephritis is not an infrequent result. These patients should be put to bed and carefully watched. When possible, it is desirable to spend the winter and early spring months in a warmer climate.

*Drug Treatment.*—The question of drugs is considered last, not because of their relative unimportance, but to emphasize the fact that they are not the first thing to be resorted to. After the measures already outlined have been instituted, vasodilators may be tried, and if the pressure can be lowered without occasioning any untoward symptoms, they are of much value. Save in extreme cases, where immediate results are desired, it is a mistake to resort to them before regulating the diet and habits.

No one vasodilator can be used in all cases, as results will sometimes be obtained with one, but not with the other. Sodium nitrite and erythrol tetranitrate are probably the most used where prolonged effects are wanted. Lawrence[2] found that vasotonin not only did not reduce tension as its champions claimed, but in certain instances the pressure was raised. The lowering of blood pressure from venesection is very marked and persists for a much greater length of time than that from any drug. Its prompt performance may be lifesaving. In arterial crises, amyl nitrate or the spirits of glonoin dropped on the tongue may give immediate relief. I once had a patient, an old lady subject to spasm of the cerebral arteries, who required from 10 to 15 drops of glonoin before the desired result was obtained. Iodide of potassium has been extensively used in cases of hypertension, but it is not altogether clear just how it acts, nor is there unanimity of opinion as to its effect. There is some evidence that it diminishes the viscosity of the blood. There are those who assert that it lowers blood pressure and the results obtained by Matthew[14] certainly bear out the contention, but there are many excellent men who have failed to obtain this effect. It is generally conceded that it will lower the pressure in lead poisoning, and its value in syphilitic endarteritis is thoroughly estab-

lished. It is quite possible that there is an underlying latent syphilis in a much larger percentage of patients with hypertension than we have hitherto supposed. By means of the Wassermann and luetin tests, it has been shown that a very high percentage of the sclerotic changes at or near the aortic orifice are of syphilitic origin. Good results sometimes appear to be obtained by the prolonged used of a small dose of potassium iodide for many months at a time. The newer preparations of the organic iodides are apparently inferior to the inorganic salts. The thyroid preparations have some advocates, but in a very limited experience, I have not seen any good results. I have had no personal experience with high frequency electricity in these cases. It is stated that not only does the blood pressure fall, but that a feeling of well-being persists for several days. There are many who have not obtained these results. Small doses of the bromides are indispensable in the case of the very nervous.

When it is evident that the heart is no longer adequate to maintain the struggle, digitalis is invaluable. It does not increase the blood pressure in these cases, and, in fact, I have seen the pressure lowered as the heart action improved after vasodilators had been ineffectual.

*Conclusion.*—In about 90 per cent. of patients with persistent hypertension, there is a pathological process in either kidney or arteries. The essential pressure in these individuals is materially higher than in health and any attempt to reduce it to the so-called "normal" is a hazardous procedure. A considerable part of the hypertension, however, is often of the so-called "incidental" sort which is caused by the activities of life and various endogenous and exogenous toxins.

The success we achieve in the treatment of hypertension depends to a large degree on our ability to reduce this incidental pressure. And so it is that we must preach the doctrine of moderation in all things—in eating and drinking, in play and in work. We rush madly about in pursuit of that will-o'-the-wisp, success, not realizing that most of us will view from Pisgah the Land of Promise, but not enter therein because our wornout bodies will not carry us thither.

# POSTMORTEM OPHTHALMOSCOPY: SEGMENTARY INTRAVASCULAR COAGULATION.

By MORRIS H. KAHN, M.D.,

NEW YORK.

RESIDENT PHYSICIAN, PRIVATE PAVILION, MOUNT SINAI HOSPITAL.

Stimulated by the presence of a curious phenomenon that it fell to my lot to observe postmortem in a case in which I practised ophthalmoscopy, I proceeded to verify the findings, and have noted certain facts which may prove of considerable interest.

In the last agonal glance there usually spontaneously occurs a marked dilatation of the pupils. Sometimes, however, the dilatation is but little, if any. Kobert[1] says: "The pupils in the cadaver are usually dilated, but may in certain cases of poisoning (with belladonna, hyoscyamus, stramonium) be enormously dilated. Abnormal narrowness of the pupil in the cadaver occurs in certain cases, but by no means regularly, after poisoning by morphine or opium. After the internal administration of poisons which on instillation cause a contraction of the pupil (muscarine, pilocarpine, physostigmine, arecoline, nicotine) no case of pronounced miosis in the cadaver has ever yet been observed.

In this study, when mydriasis was present, examination was made as usual with the electrical ophthalmoscope. Both the direct and indirect methods were employed. When the pupils remained contracted after death, they were dilated with a few drops of a solution of atropine or homatropine. As was noted by Grœnouw,[2] this was feasible before iridal rigor set in, viz., three to four hours after the patient ceased to breathe. In several cases the mydriasis brought about for the purpose of antemortem examination was taken advantage of in further study.

When the eyeball is left exposed for some time after death, drying of the cornea takes place. The opacity resulting can be overcome by moistening with water. Or, when a mydriatic is needed, the latter serves a double purpose. A method which may be used to advantage is examining the fundus of the eye through a glass slide overlying the cornea, separated from it by a drop of water (Cocius). A similar method is mentioned under the name Czermak's Orthoskop.[3]

Before describing the phenomenon which constitutes the object of this paper, it will not be amiss to recall briefly the anatomy of the retinal vessels. The following paragraph from Fuchs' Textbook of Ophthalmology may therefore be quoted: "The central vessels of the optic nerve divide at the head of the nerve into a number of larger and smaller branches, which pass over its edge into the retina, where they keep on branching after the fashion of a tree trunk. They can readily be distinguished into arteries and veins. The former are of a brighter red, narrower, and run a straight course; the latter are darker, of greater caliber, and more crooked. Most frequently it happens that two main branches run upward and two downward, while only small and short twigs pass to the inner and outer sides of the disc. The region of the macula lutea is devoid of larger vessels; the larger trunks running to the outside above and below encircle it and send finer branches in toward it."

Normally, the retinal vessels are constantly filled, with slight variations in volume as result of pulsation. Postmortem, the column of blood in the ves-

sels, sustained and solid, undergoes a change which manifests itself within a limited time.

This change consists of the formation of transverse interruptions in the red color of the vessels, giving the appearance of division or striation of the blood column. These interruptions, often only few in number, are apparent chiefly in the veins and occur both near the disc and distant from it. They occur less constantly in the smaller vessels. While looking at the fundus of the eye, or during the course of frequent repeated examinations of it, one notices, from time to time, a distinct variation in the length of one or other striation. This can be made more evident by turning the head of the subject from side to side. It can be still more accentuated by pressure upon the eyeball, in both these ways modifying the retinal intravascular pressure. Firm external pressure upon the eye empties the veins in the region of the disc and also the central artery. Upon relaxation the vessels refill to their former capacity. These manipulations for a time after death, alter the size of the interruptions considerably. After about one hour no spontaneous alterations in size are noticeable. After a longer time, *i.e.* about three hours, the vascular striations are no longer influenced by manipulation and pressure. These phenomena are sometimes more manifest in one eye than in the other.

The presence of this phenomenon, I believe, depends on intravascular coagulation. Segmentary in occurrence, with consequent shrinking of the fibrin, this leads to the formation of intercoagular spaces

Fig. 2—Postmortem opthalmoscopy

containing serum. The clots in the vessels contract, and thus separate in places from each other, leaving between them the serum which is expressed in the process of congealing. In a number of cases the intercoagular intervals were not observed. In these cases, probably clotting of the distal arterial column took place *en masse;* and the serum that otherwise formed the intercoagular interval, was expressed murally. In a few of the cases presenting choked discs, no intercoagular intervals were found. Here the above-enunciated explanation is the more maintainable, drawing support from the idea that the central pressure favored coagulation *en masse*. It is likely that it is the adhesion of the fibrin to the vessel wall that finally prohibits variation by pressure, of the size of the intercoagular spaces.

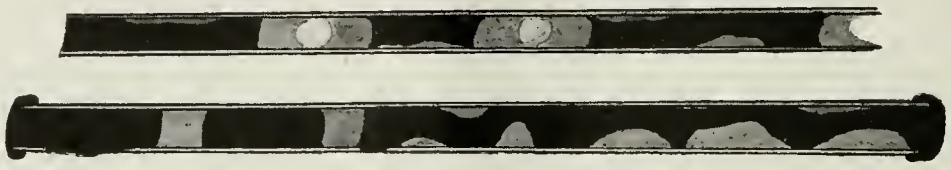

Fig. 1—Magnified in diameter.

An obvious analogy applies when we consider clotting in the large vessels of the trunk. On examination of these, the clots are found to be, so-to-speak, in segments, with serum in the intervals. When one carefully observes the peritoneal surface of the intestine postmortem or after resection, he may see that the small vessels, chiefly the venous radicals, present the interruptions corresponding to the intercoagular spaces. This appearance, due to intravascular clotting, may be found intravitam in embolism or thrombosis of the mesenteric vessels.

In the web of the frog's foot, where the blood-current affords elementary demonstration, no note is to be found of the appearance presented after the circulation ceases and intravascular coagulation takes place. I have endeavored in this relation to ascertain whether in invertebrates the blood clotting is evidenced by a microscopic picture analogous to the above described. No mention of the occurrence is made in the few volumes on invertebrate zoology that I have consulted.[4] Experimentally, I have not been able to satisfy myself that the phenomenon is to be seen.

*In vitro*, segmentary coagulation can be produced, but not without difficulty. Given the conditions comparable to those existing in small vessels, the blood clots usually with the expression of serum along the wall, not with the formation of intercoagular spaces. We made use of the glass tubes

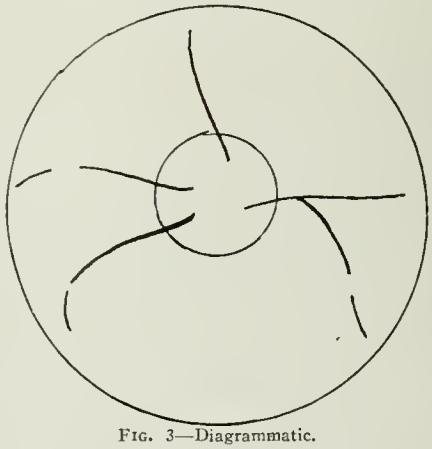

Fig. 3—Diagrammatic.

of Sabrazes and McGowan.[5] I tested this repeatedly with normal and abnormal blood, in several cases of delayed coagulability with jaundice, and in one case of hemophilia in which fibrin showed itself only nineteen minutes after the blood was drawn. Lowering or raising the temperature of

one part of the tube was of no influence. In the tubes in which the blood was allowed to flow in with interspaces of air, however, there was often intercoagular lodgment of the serum. When the glass capillary tubes were filled completely with a rapidly coagulable blood, the ends then sealed with paraffin, and the tubes suspended vertically, the irregular shrinking of the fibrin gave the appearance of segmentary coagulation. This became evident after twelve hours. (See Fig. 1.)

In a series of papers on "The Human Eye in Health and Disease as Seen with the Ophthalmoscope," C. Bader[6] writes that he has made "observations on the living and dead," and states that they "show that certain forms of cerebral disease are accompanied by visible anomalies of the optic nerve where it passes through the tunic of the eyeball. Among the anomalies the most conspicuous are disturbances in the blood vessels of the retina and changes in the connective tissue of the optic nerve." The author does not imply knowledge of the postmortem phenomenon here described. Nor has a diligent perusal of the recent literature on ophthalmoscopy revealed mention of the occurrence postmortem of segmentary coagulation.

I shall in brief present the details of the findings in three cases:

Case I.—R. F., æt. 51 years, was admitted to the service of Dr. Manges, in the Mount Sinai Hospital with a history of one week's illness. The urine showed much albumin, numerous casts, and also a high percentage of sugar. Rigidity of the neck and a slight Kernig sign prompted a lumbar puncture. The spinal fluid was purulent with numerous pneumococci. The patient died the following day with signs of consolidation at the left pulmonary base and pulmonary edema.

Postmortem Ophthalmoscopy. The pupils had been dilated with homatropine solution previously. The intercoagular spaces were first seen forty-five minutes after death (patient ceased to breathe at 1.15 A.M.) The discs were very pale but the outlines were distinct. The vessels showed the characteristic interruptions in the blood column, the intervals varying in length from one to three millimeters. For a short time after, spontaneous movement (clot-contraction probably) was seen. After one hour, this no longer took place. Three hours after death, no variation in the size of the intercoagular intervals occurred even on pressure; the picture returning the same appearance after as before manipulation. (See Fig. 2.)

Case II.—Y. T., æt. 15 years, in the service of Dr. Manges, was the victim of a rapidly progressing leukemia. Several months before, the fundi of the eyes were found to be the seat of neuroretinitis with hemorrhages.

Postmortem Ophthalmoscopy. The pupils dilated spontaneously. The discs and retinæ were of an extreme pallor, the whiteness gradually blossoming into the red color of the retinal periphery.[7] The retinal vessels were very thin and showed, with marked contrast, the intercoagular intervals. (See Fig. 3.)

Case III.—A. N., æt. 44 years, died of septicemia with *Staphylococcus aureus*[8] proven by blood culture.

Postmortem Ophthalmoscopy. In both eyes, chiefly in the right, there were noticeable with great distinctness the coagular intersections. What may appropriately be spoken of here is the formation of the intercoagular intervals in many cases very shortly after death. Thus, in the last case, while the observation was being made five minutes postmortem, there was to be seen a transverse cleavage of the upper outer retinal branch, with the formation of an intercoagular space. The poor state of the circulation which existed for hours before death can be taxed to account for this early occurrence. During this time the circulatory stasis favored later coagulation.

It is possible that the subject of my discussion may find a chapter in forensic medicine. In order to establish the exact average time for the development of the segmentary coagulation after death, and in order to define the time limits of its occurrence under differing conditions, such as after drowning, etc., such cases will have to be studied. This part of the topic must be relegated to the realm of those whose opportunities permit its fruitful elaboration.

I take the opportunity to thank Dr. Max Kahn of the Department of Biological Chemistry, Columbia University, for his encouragement and kind suggestions during the course of this study.

## Medicolegal Notes.

**Recovery for Medical Services as Damages.**—In an action for personal injuries caused by the defendant's negligence it is held that the plaintiff can only recover the fair value of such services so far as they were rendered in the treatment of physical ills resulting from the defendant's tort, and that he cannot recover unless the services rendered were such that the doctors, if plaintiffs in an action against him, could recover and that the right of action is measured only by his legal obligation to pay them. —Hunt v. Boston Terminal Co., Massachusetts Supreme Court, 98 N. E. 786.

**Evidence—Effect of Cocaine.**—In a prosecution for unlawfully selling cocaine, the opinion of a medical expert, who was a pharmacist as well as a doctor, that a powder in a package, which he tasted was cocaine, was held to be properly admitted, although he testified that he could not tell the difference between cocaine and epsom salts, except by making actual tests. He had previously described fully the effects of cocaine and the effect of the powder he had tasted.—State v. Burno, North Carolina Supreme Court, 74 S. E. 464.

**Statements to Physicians as Evidence.**—While statements of a party injured, narrative of past conditions or suffering, made to the ordinary witness are inadmissible, a physician may testify to such statements given by a patient in relation to his condition, symptoms, sensations, and feelings, both past and present, when such statements were received during and were necessary to an examination with a view to treatment, or when necessary to enable him to give his opinion as an expert witness. The evidence is admissible for the purpose of affording the jury the means of determining the weight to be given to the opinion of the physician, not as evidence to prove the actual condition of the patient, and the jury should be cautioned upon the point.—Acme Cement Plaster Co. v. Westman, Wyoming Supreme Court, 122 Pac. 89.

**Cross-Examination.**—In a will contest case the testator's physician was examined as a nonexpert witness. He was not asked on direct examination to give any opinion touching the condition of the testator's mind. It was held that a question on cross-examination, calling for such an opinion, was properly excluded as not proper cross-examination.—Crawfordsville Trust Co. v. Ramsey, Indiana Supreme Court, 98 N. E. 177.

## BERIBERI AND INFANTILE BERIBERI AND THEIR TREATMENT.

PERHAPS the most interesting of all the interesting and instructive matter contained in the report of the Surgeon General U. S. Army for 1912, is that which refers to beriberi. Investigations as to the causation of the prevalent tropical disease have been during recent years numerous and exhaustive. British observers have vied with American investigators in endeavoring to trace to its source the origin of beriberi and thereby to be able to devise means to stamp out this most distressing and harmful Far Eastern malady. Although there are those who hold that the cause has been practically discovered, really this is not so obviously apparent as some would have us believe. True, it is known that among Oriental peoples, accustomed to make of rice their staple diet, beriberi will occur if the highly polished or highly milled rice is used, and that the disease will disappear or will not occur when the undermilled variety is eaten. But there is no absolute concensus of opinion among authorities as yet, with regard to the exact constituents of rice whose presence brings on beriberi. In the last report of the Surgeon General it was shown that fowls fed on highly milled rice developed a polyneuritis in the great majority of cases. It was then known that the salts of phosphorus and potassium in the rice do not of themselves prevent beriberi, but it was believed that the amount of these salts present could be taken as an index of the beriberi preventive quality of the rice. It is stated in the present report, that some samples of undermilled rice have since been examined which retained almost the entire pericarp and which undoubtedly would prevent beriberi, and yet these rices on analysis were shown to contain a percentage of phosphorus pentoxide, as low or lower than that contained in some specimens of highly polished rice which were analyzed by the same chemist. The Army Board for the Study of Tropical Diseases is therefore of the opinion that the character of the soil may affect very materially the phosphoric contents of rice as it does in the case of other grains. The Board is further of the opinion that the amount of amido-nitrogen may be as reliable an index as the salts of phosphorus and potassium.

The conclusions in a report made by the Board in January, 1912, were as follows: (1) These experiments all substantiate the theory that polyneuritis gallinarum and beriberi are caused by the deficiency of some as yet unknown substance in the food. It has been previously shown that this substance is not phosphorus. (2) Kohlbrugge's theory that beriberi is caused by an acid intoxication, which is due to the fermentation of rice by various saprophytic bacteria contained in the kernel, must be regarded as untenable. (3) To the list of substances which have been shown in previous papers of the board to be of no importance in preventing neuritis of fowls, there may now be added the following: Nitrogenous compounds, such as arginin, histidin, asparagin, and various amino acids; lipoids of the lecithin group and cholin; extract of onions. (4) The neuritis-preventing principle is absorbed by animal charcoal and the filtrate through the charcoal will not prevent neuritis. After absorption the active principle cannot be removed from the charcoal by macteration with water, absolute alcohol or ether. (5) The administration of large quantities of sodium chloride failed to produce edema in fowls suffering from polyneuritis. (6) Five cubic centimeters of the extract prepared by the board, equivalent to five grams of rice polishings, is sufficient to protect fowls subsisting upon polished rice. Two and one-half cubic centimeters, equivalent to 2.5 grams, of polishings is insufficient to confer complete protection from polyneuritis. Thus it would appear that beriberi is a disease, the causation of which is due to improper diet or rather to a deficiency of some substance in the food but that such substance has not been identified yet.

In the Philippines, there is a very prevalent disease among infants, which is looked upon by many observers as infantile beriberi. The Board has been treating some selected cases, fifteen infants, by administering to them extract of rice polishings directly while permitting them to continue breast feeding. With one exception all these infants were under three months of age. The disease has usually been ushered in with vomiting, which after a few days was followed by great restlessness, sleeplessness, continual whining and later by dyspepsia, increased cardiac action, and edema of the face and legs. Later still, oliguria and aphonia developed in many of the patients. It should be stated that the mothers of all these infants had symptoms of incipient or marked beriberi. The infants were given 20 drops of the extract every two hours while awake and the results were truly marvellous. The vomiting stopped in 24 or 36 hours. The child who has not passed any urine for several days, urinates five or six times freely. The edema disappears in the course of a few days. At the end of a week or in less time the patients are completely cured, with the aphonia, probably due to the fact that the aphonia is caused by degeneration of the pneumogastric nerves which only slowly regenerate. It can be said that this extract is a "cure" in the true sense of the word. The final conclusion of the Board is "One can hardly fail to be convinced that beriberi is due to a deficiency of some as yet unknown substance in the food and that infantile beriberi is produced in those children who receive milk from a mother suffering from such a de-

ficiency otherwise, how can the remarkable effects of the extract treatment be accounted for? We regard our work with infantile beriberi as the final link in the chain of evidence which has been built up from experiments on men and animals, and which proves that an improper diet, usually one consisting of highly milled rice, is responsible for the development of beriberi."

The public and the medical profession alike are too apt to forget the debt of gratitude which is owing to army medical officers of this country for their work in connection with tropical diseases. In Cuba, in Hawaii, in Porto Rico, and in the Philippines, the U. S. Army Medical Corps has done yeoman service in investigating and in laying bare the origin of several obscure tropical maladies and consequently pointing out a mode of successful treatment. If they succeed in eradicating beriberi, which seems probable, they will have performed another inestimable service to mankind.

## THE FRIEDMANN SALE.

The mission of Dr. Friedrich Franz Friedmann to the United States has been accomplished and our early conjectures as to its purely commercial object are fully confirmed by the announcement of the sale of the American rights in his alleged remedy to a stock company. According to the terms of the sale, this "scientist," as he is called by a New York newspaper which applauds the transaction, receives $125,000 in cash and a one-third interest in some thirty-five or forty "Friedmann Institutes" to be planted in as many States. This scheme of independent "institutes," which recalls that of another "scientist" with commercial instincts, the late Dr. Keeley, has been adopted apparently to nullify the anticipated action of the Public Health Service in forbidding the sale of the vaccine. As the stuff will be made in each "institute" and sold there it will not be carried in interstate commerce, so the Federal Government cannot interfere. When Dr. Friedmann first came to New York, we thought he had been ill advised, but we were looking at the matter from the side of ethics; we now see, looking at it from an entirely different side, that he has been very well advised.

Whether the purchasers of this secret remedy have been equally well advised time will show. They had to jump quickly, since other manufacturers had been approached and some one of them might at any time conclude a deal, and it is possible the leap was taken without the precautionary look. The results of the New York experiments would hardly seem to warrant an outlay of $125,000 for the Friedmann secret, but then the stuff has been widely advertised and moribund consumptives are hopeful and credulous. There has, as yet, been no official report on the experiments with the turtle bacillus culture in the hospitals in this city, but it is very generally known among medical men, if not among the laity, that the results have been not at all satisfactory—except to Dr. Friedmann. Reports from Berlin also are very far from giving support to the earlier statements that the patients treated there are doing well. On the contrary, many of the survivors are stated to be doing very ill. One of the reported cases, indeed, is of most serious import and it at once brings up the question whether the turtle bacillus is as innocuous as Friedmann has claimed and as has been generally believed—apparently only on his say-so. This case, referred to by correspondents of the *Southern California Practitioner* and the *Lancet-Clinic*, was that of one of those who died after treatment with the Friedmann vaccine. The autopsy showed that he had miliary tuberculosis, and fresh tubercles were found in the gluteal muscles, where the injection of the assumed nonvirulent bacilli had been made, and also in the glands receiving the lymph from that region, but the corresponding parts on the opposite side, where no injection had been made, were free from tubercles. Only one of Friedmann's New York patients, so far as we know, has yet died.

## SOME MEDICAL ACTIVITIES IN RUSSIA.

The opinion has prevailed extensively in the past and still abounds to far too great an extent that little or nothing transpires in great cities of remotely situated countries which makes for medical progress. This does not apply perhaps to the colonial cities of the great culture nations, but to such independent communities as Russia and the great South American republics. The epoch-making work of Pavlov in St. Petersburg filtered but slowly into medical teaching despite the fact that his book was well translated at an early stage of his work. It was simply a case of "nothing good coming out of Nazareth."

A letter from Moscow to the *Berliner klinische Wochenschrift*, March 31, which deals with the recent work of various Russian medical societies, will serve to illustrate the error of this attitude. The fact is only too well realized that implantation of the ureters into the intestine is almost universally followed by pyelitis or pyelonephritis. Ilyin reported to the Pirogoff Surgical Society that he had successfully met this sequel by subjecting these patients to coli vaccination. As a curative proposition the remedy was successful in three out of ten cases. Two were completely cured and another greatly improved. Ilyin next tested an immunizing or prophylactic application of the same principle upon animals with such a degree of success that in future whenever he implants ureters into the bowel he will institute prophylactic treatment of this character.

At the representative medical society of Sebastopol Kogan reported progress with the well-known Gabritchevsky protective inoculation against scarlet fever, which is a purely Russian contribution to preventive medicine dating from 1908. It was learned that reinoculation of children gives uniformly negative results, thus testifying to the protection afforded. All children inoculated between 1908 and 1911 were proved immune. An epidemic then appearing in an asylum for children, but 2 out of 62 inoculated contracted the disease. Numerous other papers show the tendency of the medical men in Russian cities to give prompt and full try outs to all new resources, whether diagnostic or therapeutic.

These cover phases of serodiagnosis and serotherapy, the use of radium, salvarsan, and neosalvarsan, various types of vaccinotherapy, tests for renal insufficiency, scopolamin narcosis, etc., many of these resources having been tested on a grand scale.

## OUTLOOK FOR DIPHTHERIA AS A FOLK PLAGUE.

A PARTIAL conquest of a pestilence appears invariably to determine new and unforeseen problems. Diphtheria, at first of epidemic incidence, only became endemic in culture countries about sixty years ago and its endemicity shows no sign of abatement. The partial conquest has been twofold. First, the bacterial cause has been demonstrated, and second, by a serum the percentage of mortality has been greatly reduced. The type of the disease has undergone no fundamental change and is now mild, now severe. The serum has prevailed over the most severe outbreaks. If as is claimed the malady is even more transmissible than before the days of Loeffler and Behring, the low percentage mortality may in time come to be offset by the total mortality; while the expense of immunization and of isolation may become almost prohibitive. The outlook for the disease was discussed last December before the Gesellschaft für Natur- und Heilkunde of Dresden (*Münchener medizinische Wochenschrift*, March 18). Conradi and Schanz each read papers on the subject. The rigid isolation practised in actual diphtheria does not avail against the insidious transmission by walking cases and carriers. Conradi knows of but one resource universally available. If every one sick or well, suspect or non-suspect should disinfect the nose, throat, and nasopharynx with some known and safe germicide, more might be accomplished within a limited time than by all other resources combined. At least this plan should be thoroughly tested.

From another viewpoint the bacteriological diagnosis, so indispensable in connection with isolation and treatment, is much prejudiced by the fact that while the true Klebs-Loeffler germ is never found outside of human secretions, the false counterpart bacillus is ubiquitous. The two can be absolutely distinguished solely through the toxicity of the former, and small laboratory animals are not always available. Schanz states that some profound reason must be to seek for this acquired toxic property of an apparently universal harmless microorganism, which even when toxic may be but mildly so and fails to act at all upon many organisms. What is the nature of the diminished resistance? To acquire this knowledge must be the task of the immediate future.

### HAS THE SPIROCHETE A RESISTANT STAGE?

NEARLY two years ago (July 8, 1911) we had occasion to mention in this column the work of Balfour concerning the spirochetosis of Sudanese fowls. Balfour had observed that under certain unfavorable conditions these spirochetes discharged small, highly refractile bodies immediately before death. Balfour was led by his researches to believe that these globules possessed the power of invading the erythrocytes and of later developing into adult spirochetes, and was inclined to ascribe to this power the resistance which such infections offer to treatment. The subject is one of the greatest importance and naturally has been taken up by a number of investigators. Recently Gleitsmann (*Centralbl. f. Bakt.*, vol. lxviii, p. 31) has published the results of a number of his experiments from which he is forced to the conclusion that Balfour was wrong. He reaffirms the reality of these bodies but asserts positively that they are not resistant forms of this particular variety of spirochete. Similar bodies have been found in the blood of healthy birds and in the end the proof must lie in their infectiousness. So far all culture experiments have been negative and Gleitsmann is of the opinion that the inoculations have given results that are at least doubtful. Whether these globules are merely degeneration forms of the organism or constitute a stage in the development of some other variety of spirochetes is a question that remains unanswered, but he firmly maintains that up to the present time there is no good proof of their infectiousness.

## News of the Week.

**Health of the Canal Zone.**—During the month of February, 1913, there occurred 42 deaths from all causes among the employees in the Canal Zone, giving an annual average death rate per thousand of 9.11. Of the total number of deaths, 27 were due to disease and 15 to violence. The annual average death rate per thousand in the cities of Panama and Colon and the Canal Zone, including both employees and civil population was 21.10 for the month, a decided increase as compared to February, 1912, when the rate was 16.33. Among employees, the deaths from the principal diseases were as follows: Abscess of liver, entamebic, 1; hemoglobinuric fever, 1; pneumonia, 4; malaria, 1; tuberculosis, 5. On December 15, 1912, all the sick camps were closed, with the exception of those located at Culebra, Toro Point, and Porto Bello. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

The report of the Department of Sanitation for the year 1912, gives the total number of deaths as 467 among 50,893 employees, or an annual death rate per thousand of 9.18. This is lower than for any previous year, and presents a startling contrast to the 1906 rate of 41.73 per thousand. The death rate among white employees from the United States from disease was 3.25 per thousand, while the total death rate for the year for this class of employees was 5.52 as against 5.14 in 1911. The inclusion of American women and children raises the death rate of Americans from disease to 4.22; and the inclusion of the officers and men of the United States Army and Marine Corps stationed on the Canal Zone and their families lowers the rate to 3.86 per thousand. The death rate from disease in the army for the calendar year 1911 was 2.66 per thousand. The principal causes of death during the year were as follows: Typhoid fever, 4; dysentery, 7; malaria, 20; nephritis, acute and chronic, 36; pneumonia, 57; tuberculosis, all forms, 70; external violence, 143. The death rate for the total population of the cities of Panama and Colon and the Canal Zone for the year was 20.49, the lowest on record with the exception of 1909 when the rate was 18.19. One case of yellow fever, on a ship

from Guayaquil, Ecuador, was isolated in Santo Tomas Hospital, and died there on July 14. With this exception, no cases of yellow fever, plague, or smallpox occurred on the Isthmus during the year. The improved conditions as regards deaths from malaria among employees in the Canal Zone continued through the year, and the admission rate to hospitals showed a steady decline from 821 per thousand in 1906, to 110 per thousand in 1912.

**Plague in Manila.**—Five deaths from bubonic plague in the city of Manila have resulted since January 1 of this year, and several new cases have developed recently. The Manila Board of Health has ordered the employment of fifty rat-catchers in addition to those already employed to free the city from the rodents.

**City Death Rate.**—For the week ending April 19 the death rate in New York was 15.22 per thousand, the total number of deaths being 1,567, as against a rate of 15.75 for the same week of 1912.

**Hospital Apportionments.**—The Hospital Saturday and Sunday Association last week apportioned funds amounting to $105,000 collected during the year, among forty-six private hospitals in New York. The distribution, according to the rules of the association was based on the number of days of free treatment given by each hospital. The largest apportionment went to the Montefiore Home, which for 166,036 days of free treatment received $10,500. Mt Sinai Hospital for 108,943 days received $9,129.42, and St. Luke's Hospital, standing third on the list, received $6,148.41 for 73,370 days. The other large hospitals received the following amounts:

| Hospitals | Free Days. | Appropriation. |
|---|---|---|
| New York | 71,279 | $5,973.18 |
| German | 51,302 | 4,299.11 |
| Post-Graduate | 44,528 | 3,731.45 |
| Roosevelt | 43,988 | 3,686.19 |
| Lincoln | 32,803 | 2,748.89 |
| Lebanon | 32,399 | 2,715.04 |
| Beth Israel | 31,751 | 2,660.73 |
| Flower | 15,551 | 1,303.17 |
| French | 14,098 | 1,181.41 |
| St. Mark's | 10,849 | 909.15 |
| Hahnemann | 10,431 | 874.12 |

A summary of the gifts under four heads follows:

| | Free Days. | Appropriation. |
|---|---|---|
| General hospitals | 587,371 | $49,323.85 |
| Special hospitals | 191,149 | 16,082.66 |
| For women and children | 266,724 | 22,376.00 |
| Convalescents and incurables | 246,197 | 17,217.49 |

**The Paul Kimball Hospital,** in Lakewood, N. J., was opened for inspection on Monday and Tuesday of this week, and for the reception of patients on Thursday, May 1.

**War on Cancer.**—Steps were taken in New York on April 22 toward the formation of a National Anti-Cancer Association on lines somewhat similar to those of the Anti-Tuberculosis Association. The leading purpose of the organization is the education of the public to recognize the early symptoms of the disease, and the general plans provide for magazine articles, leaflets to be distributed through the Department of Health, social workers, and women's clubs, and lectures. A committee on organization was appointed and cooperation of the Congress of Physicians which meets next month in Washington will be asked for. The movement has already interested a number of prominent physicians, laymen, and laywomen.

By the will of Henry Rutherford of New York, who died last February, the sum of $200,000 is bequeathed to the Rockefeller Institute of Medical Research, the "income to be applied to investigations into the causes and nature of the disease known as cancer, and the methods of its prevention and treatment."

**Dr. William H. Welch** of Johns Hopkins University was elected president of the National Academy of Sciences at the closing session of the society's fiftieth annual meeting in Washington on April 23.

**Dr. A. Sturmdorf** has been appointed Clinical Professor of Gynecology in the New York Polyclinic Medical School and Hospital.

**Memorial to Dr. Billings.**—On April 25, in the Stuart Gallery of the New York Public Library, a meeting was held to commemorate the life and services of Dr. John Shaw Billings, late director of the library, who died on March 11. Addresses were made by Dr. S. Weir Mitchell, who told of Dr. Billings' services as a surgeon in the United States Army during the Civil War; by Sir William Osler, who spoke of his work in the library of the Surgeon General's office; by Dr. William H. Welch, who paid tribute to his ability as a hospital organizer; by Mr. Andrew Carnegie, who was for many years associated with Dr. Billings in the work of the New York Public Library, and by Mr. Richard R. Bowker, representing a number of associations of librarians.

**State Health Commissionership.**—Dr. Hermann M. Biggs of New York has signified to Governor Sulzer his willingness to accept the appointment as State Commissioner of Health of New York under the proposed law now before the Legislature which provides for a reorganization of the Department of Health and gives increased powers to the commissioner.

**Gifts to Charities.**—By the will of the late Patrick Goodman of New York, St. Francis' Home for Chronic and Incurable Invalids receives $500, and the Misericordia Hospital and St. Joseph's Hospital for Consumptives, $250 each.

The Presbyterian Hospital, New York, receives $15,000, and St. Vincent's Hospital, $7,000, by the will of the late Mrs. Cornelia Eaton of this city.

A bequest of $5,000 to the Methodist Episcopal Hospital, Brooklyn, is contained in the will of the late Hannah M. Rockwell of this city.

**Dartmouth Drops M.D.**—The Trustees of Dartmouth College have announced that after the graduation in 1914 of the present junior class of the medical school the last two years of the course in medicine will be discontinued. The first two years in medicine will be reorganized into a department of the college, and work in this department will be credited toward the requirements of the degree of bachelor of science. After the completion of the two years, students will be eligible for advanced standing in other medical colleges giving the degree of M.D. The Trustees have been forced to take this step because of the impossibility of obtaining sufficient clinical material in Hanover for the practical work necessary. The school was founded in 1798, and is the fourth oldest medical college in the country. It has had many prominent men on its Faculty, the most notable being Dr. Oliver Wendell Holmes, who became professor of anatomy and physiology in 1838.

**Pennsylvania Alumni.**—At the annual dinner of the Philadelphia Branch of the Alumni Society of the Medical Department of the University of Penn-

sylvania on April 18, Dean Pepper acted as toastmaster, and addresses were made by Provost Edgar Fahs Smith, Dr. Richard C. Cabot of Boston, Dr. Lewis H. Taylor of Wilkesbarre, and Prof. John G. Clark. The following officers were elected for the ensuing year: *President,* John B. Deaver; *Vice-Presidents,* John K. Mitchell, Richard C. Norris, S. McC. Hamill, Lewis H. Taylor, Casper W. Sharples, Walter R. Weiser, and Alexander R. Craig; *Historian,* William Pepper; *Secretary and Treasurer,* G. Morris Piersol; *Executive Committee,* James Tyson, George E. de Schweinitz, George C. Stout, Allen J. Smith, Charles W. Burr, Lewis H. Adler, Jr.; George G. Ross, B. A. Thomas, Fred H. Klaer, and Henry P. Brown, Jr.

**The Ninth International Congress on Medical Hydrology, Climatology, and Geology** will be held in Madrid, Spain, from October 15 to 22, 1913. The object of the congress is to study all problems connected with the above sciences, to bring together investigators and scientific men of all countries, and to make known to all foreigners the hydrological, climatological, and geological richness of Spain. The work of organization is under the direction of a central committee composed of the officers of the congress, and all communications regarding it should be addressed to the Secretary General, Dr. Rosendo Castells, Madrid.

**State Conventions.**—The Florida State Medical Association will hold its annual meeting at Miami on May 14, 15, and 16, under the presidency of Dr. J. L. North.

The Kansas State Medical Association will meet in Topeka on May 7 and 8.

The date of the meeting of the Kentucky State Medical Association has been changed from May 13 and 14 to May 20 and 21. The convention will be held at Paducah.

The Oklahoma State Medical Association will hold its annual meeting at Enid on May 13, 14, and 15. Dr. Claude A. Thompson of Muskogee, secretary of the society, is preparing an interesting programme. Dr. James L. Shuler of Durant is the president of the society.

**American Proctologic Society.**—The fifteenth annual meeting of the American Proctologic Society will be held in Minneapolis, Minn., on June 16 and 17, 1913, under the presidency of Dr. Louis J. Hirschman. Details of the programme, etc., may be obtained from Dr. Lewis H. Adler, Jr., 1610 Arch Street, Philadelphia.

**American Gastro-Enterological Association.**—The sixteenth annual meeting of the Gastro-Enterological Association will be held at the New Willard Hotel, Washington, D. C., on May 5 and 6, 1913. Dr. J. Kaufmann of New York, president of the association, will speak on the rôle which functional disorders play in the pathology of the stomach, and a number of other papers will be presented. Dr. Franklin W. White, 322 Marlboro Street, Boston, is the secretary of the society.

**Medical Society of the State of New York.**—At the annual meeting of this Society, held this week at Rochester, the following officers were elected: *President,* Dr. William Francis Campbell of Brooklyn; *First Vice-President,* Dr. W. Stanton Gleason of Newburgh; *Second Vice-President,* Dr. Gerrit F. Blauvelt of Nyack; *Third Vice-President,* Dr. Myron Botsford Palmer of Rochester; Secretary, Dr. Wisner R. Townsend of New York; *Treasurer,* Dr. Alexander Lambert of New York. *Committee on Scientific Work,* Dr. Thomas J. Harris of New York, Chairman; *Committee on Legislation,* Dr. Lewis Knode Neff of New York, Chairman; *Committee on Public Health,* Dr. Joshua M. Van Cott of Brooklyn, Chairman; *Committee on Arrangements,* Dr. Charles H. Richardson of New York, Chairman.

*Place and Time of the Next Meeting:*—New York City, April 28, 29, and 30, 1914.

**Obituary Notes.** — Dr. Charles Hunton Knight of this city died on April 28, after a long illness. He was born in Massachusetts in 1849 and was graduated from the College of Physicians and Surgeons, New York, in 1874. He served a term as interne at Roosevelt Hospital and then was appointed chief of the house staff of the New York Hospital when its new building was opened in Fifteenth street. Soon after entering practice he turned his attention to laryngology and soon attained a prominent position among the specialists in that branch. He was a member of the American Laryngological Association, of the American Academy of Ophthalmology and Oto-Laryngology, of the American Academy of Medicine, the New York Academy of Medicine, the Medical Societies of the State and County of New York, and the American Medical Association. He was consulting laryngologist to the Manhattan Eye, Ear and Throat Hospital, the State Hospital for Crippled and Deformed Children, and the Stonywold Sanatorium. He was for a number of years professor of laryngology at the Cornell Medical College in New York City.

Dr. J. Lester Carney of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1888, and a member of the New York State and Kings County Medical Societies, died at his home on April 22, aged 62 years.

Dr. Howard C. Rice of St. Joseph, Mo., a graduate of the Ensworth Medical College, St. Joseph, in 1910, died at his home from pneumonia on April 9, aged 30 years.

Dr. James Van Brakle of Forest Hills, N. Y., a graduate of the New York University Medical College in 1865, and for forty years a practicing physician of Brooklyn, died at his home on April 14, aged 85 years.

## Correspondence.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

HEALTH WEEK—TUBERCULOSIS DISPENSARIES—USES OF TUBERCULIN—MEETING OF PANEL PRACTITIONERS — SPECTRAL ANALYSIS — CENTENARIAN MEMBER OF COLLEGE OF SURGEONS—ANTI-VIVISECTIONIST'S ACTION—OBITUARY.

London, April 11, 1913.

This week has been kept as a national "Health Week," so designated in response to the proposal of a committee organized to bring home to the people the comfort they may secure for themselves in their own homes by care and attention to hygiene. This is the second year of the movement and sixty towns have taken part in it, against forty which did so last year. In London it is next to impossible to organize so complete a combination as in provincial towns, but isolated attempts have been made. London, in fact, seems to have no unity but to be rather a conglomeration of localities with little in common. The national "Health Week" committee desire to compel public attention throughout the whole week to local conditions affecting the health of the inhabitants and their homes. Death rates, zymotic disease rates, housing problems, school hygiene, smoke

abatement; in fact, all problems relating to the person or the home are within the program, which embraces whatever concerns the health of the individual, and is to be dealt with from the personal aspect rather than that of the State.

It may be said that the "Health Week" began on Sunday, for special sermons were preached in connection with it in a considerable number of places, and the succeeding days have been signalized by "health talks," conferences, lectures, exhibitions, and so on. In some schools competition has been held for prizes offered for the best essay on "What Must I Do To Be Healthy?" In crowded places meetings for mothers and lessons on mothercraft have been given and even baby shows and competitions in baby dressing have been organized. Health literature has been distributed at various assemblies and to school children. In Dublin an exhibition was opened by the Lord Lieutenant. The same practical method was adopted at Newcastle-on-Tyne, where a section was given to tuberculosis and special features to children's needs, "babyland" home nursing, cookery, and the care of the teeth. At Lewes the Mayor and Mayoress opened the week and gave a reception at the town hall, and the Red Cross Society held demonstrations. There, too, five hundred children were enrolled as members of a juvenile branch of the Women's Imperial Health Association, which carried on the work in the town.

Princess Louise, on the 5th inst., opened the new building of the Stepney and Mile End Dispensary, linking up with several others which have been established under the movement for the prevention of consumption. The fund for this one was raised in memory of King Edward by the ex-Mayor, who stated that the subscribers included the richest manufacturers and the humblest costermongers in the borough. Tuberculosis dispensaries are being erected and supported in various districts by a central fund raised for the purpose of fighting the disease in one way, but in connection with other methods. Of these the sanatorium is perhaps the most allied, or at least lends itself most easily to cooperation, although hospitals and the poor law institutions must not be overlooked. In fact, all other bodies, official or voluntary, which deal with the prevention of tuberculosis are regarded as co-workers by the promoters of these dispensaries. But here again the difficulty alluded to above comes in of organizing any scheme of administration to cover the whole of London. The health committee of the County Council is engaged on the preparation of such a scheme and is receiving support from the local sanitary, poor law, and education authorities. The philanthropic associations will certainly be forward to aid, and the asylums' board and insurance committee should be able to assist. It is generally held that the special hospitals should be the chief centers, but I think the large general hospitals and the children's hospitals should equally contribute. The question may well be considered whether the inclusion of every existing hospital, infirmary, or other institution for the sick would not tend to restrain the spending of too much money on new buildings.

At the Hunterian Society there was a discussion on the uses of tuberculin last month in which some practical remarks were interspersed. Dr. Latham said at King Edward VII Sanatorium the number of patients who lost their bacilli was 17 more per cent. of those who had had tuberculin than of those who had not. He spoke of the manifestations of tuberculosis such as in pleurisy, peritonitis, lupus, and disease of glands, joints, and bones. He held if the real nature of pleurisy in early adolescence was recognized and treated by tuberculin in sanatoriums many pulmonary cases would be prevented. He did not attach importance to the particular brand used nor did he accept the statement that bovine preparations should be used in pulmonary and human in "surgical" cases.

Dr. Grace-Calvert emphasized the point about pleurisy which was of great importance as it was so often followed—more often than not—by definite disease. Sanatorium and tuberculin treatment were complementary, the latter stimulating the production of antibodies, the former the powers of response. Most patients were fit for tuberculin if carefully watched, if kept at rest, and if the treatment was begun with small doses. He used the intensive system as he thought it increased tolerance and abolished sensitiveness as to its alleged effect of producing cavities; if it did he preferred a ring of scar tissue round an empty cavity to a mass of dead tissue containing bacilli. Dr. Linnell opposed the use of the test as dangerous and objected to causing reactions. Gentle, therapeutic doses were better. In early cases tuberculin should not be given until after a course of rest and other sanatorium methods. Then it should be started cautiously if the symptoms had subsided. It should never be looked upon as a substitute for other treatment but was of use in suitable cases, as determined by the resistance of the patient. Sanatoriums were indispensable adjuncts to the dispensary system.

A very excited—disorderly is scarcely too strong an adjective—meeting of practitioners on the panel for London was held on Tuesday afternoon. A report was about to be read when the constitution of the committee, or those so styling themselves, was called in question. Some said it originated at a meeting in January and had been working very hard as to simplification of records, representation on local committees, the pharmacopeia and administration of the Insurance Act in all points touching the profession. Cries of "what is your status?" and the committee "is as dead as the Dodo" showed the tense feeling present at the outset and flat contradiction followed statements made by some of the speakers throughout. One who said he was not on the panel was denounced as a spy and ordered to leave. Another declared the committee was a packed body and had no authority. He was contradicted and replied by offering names. The chairman spoke amid interruptions of the heavy strain the committee had gone through and declared they did and would do their best for the benefit of the profession, that the panel had come to stay, there were 1,258 on last month and they must make the best terms they could. It was then proposed and seconded to ask the same committee to continue to act for a time. This was opposed by an amendment calling for their resignation which it was asserted they had promised. A number of other amendments were proposed and discussed amid much confusion, the chairman being obliged repeatedly to call for order. Eventually the meeting resolved to appoint a new committee to represent all practitioners at present on the panel, requested those who had acted so far to make arrangements for the election of their successors who are to take office at the end of May.

Dr. J. J. Dobbie gave a lecture on the "spectroscope in organic chemistry" at the Royal Institu-

tion on April 4. He explained how some carbon compounds allow light to pass freely, others absorb the ultra-violet, and others rays of particular wave length, so that gaps or bands appear in the spectrum. Compounds in which C. was associated in rings, *e.g.* benzene absorbed particular portions of the spectrum. This method of analysis was very successful with quinine, morphine, strychnine, and atropine, and could mostly detect small quantities—say 1/500 grain of strychnine—and distinguish one from another. Moreover the method did not change or destroy the substance so that it was available for future analysis. It could also be applied to colored substances and quite recently it was determined by spectroscope analysis that the yellow coloring matter in unbleached flour was the same as that in carrots.

Yesterday at the Royal College of Surgeons the Council accorded their congratulations to the oldest member of the college, Surgeon-Major H. B. Hinton, on attaining the age of 100 years on March 7. The names of those to whom the prizes and medals were awarded were announced and other business transacted.

An action for libel against the *Pall Mall Gazette*, brought by Miss Lind-of-Agaby, editor of the *Anti-vivisection Review*, has been going on all the week and plaintiff's case is not finished.

The senior surgeon of the Queen's Hospital, Birmingham, Mr. Jordan Lloyd, died suddenly on the 4th inst. from angina pectoris. He had been to the hospital, performed several operations, and returned home, but was seized with angina a few minutes after entering his house. He was in his sixtieth year and had long held a leading position in the Midlands. He took the Fellowship of the Royal College of Surgeons in 1880. Among many important offices held by him was that of professor of operative surgery to the Birmingham University, examiner in surgery to Durham University, consulting surgeon to the Birmingham and Midlands Hospital and the West Bromwich Hospital, and he had been president of the Midland Medical Society and lecturer at the Institute. His operative skill was proverbial and the admiration of all who once witnessed it. His health had not been so good of late but his delight in his work was unabated and I fear he did not take the rest he needed.

Dr. Samson Gemmell, professor of medicine in Glasgow University and Physician to the Western Infirmary, died on the 2d inst. at the age of 65. He was closely associated for a time with the late Sir William Gairdner of whose views he continued to be the most able exponent. He will be sorely missed for he was a great teacher and well sustained the reputation of the University and the Glasgow School of Medicine. His death is supposed to have been due to cardiac failure for he had kept his usual health to all outward appearance. He had walked home from his morning visit to the Infirmary but soon after reaching his house was taken ill and died before medical aid could arrive.

Dr. W. R. Evans of Dublin died suddenly on April 7 at a meeting of the Fellowship of Christians. His sister, a lady advanced in years, died the same night from shock on hearing of the occurrence.

Yet another sudden death is reported, that of Dr. Courtenay Milwand of Cardiff, which took place yesterday from cardiac failure.

Deputy-Surgeon-General (late) John Mills died on the 1st inst. at the age of 92. He was formerly of the Bombay Army Medical Service, which he entered in 1848, retiring in 1876.

## OUR BERLIN LETTER.

(From Our Regular Correspondent.)

THE UNION OF INSURANCE PHYSICIANS IN BERLIN—INADEQUACY OF FEES—ABUSE OF PRIVILEGES OF SICKNESS INSURANCE—SAFEGUARDING THE PHYSICIANS' RIGHTS.

Berlin, March 15, 1913.

What has hitherto been regarded as impossible has come to pass under the stress of circumstances. The insurance physicians of Berlin have combined to form an organization. The significance of this can be understood if one takes into account the fact that in no other city in Germany has there been such lack of unanimity among the insurance physicians as in Berlin. The cause is apparent. Among 3,000 physicians it is not likely that one can get entire argeement when these physicians belong to different insurance offices, as is the case in Berlin. The recent "union" is to be attributed to the new insurance law. A number of organizations of insurance physicians combined to form a central body, which established rules that will govern future dealings with the insurance offices. The main subject for discussion is that of free choice of doctor versus the inflexible panels of the insurance offices. A committee has been appointed to deal with this problem. Mall, chairman of the committee, is of the opinion that it is to the interest of the insurance physicians to stick to the union, for it is uncertain whether under the new law all of the insurance offices will survive, in which event the livelihood of the physicians belonging to these offices will be jeopardized. A million people are members of the insurance offices, which fact emphasizes the power that resides in the hands of the physicians' union, power that should not be abused, however, by any excessive demands. Only a minimum of reforms need be advocated.

The principal subject that engaged the attention of the committee was taken up by Sternberg. The average annual fee given to the physician for each member of the insurance societies is five marks. This figure is not attained so far as the majority of Berlin insurance physicians is concerned, in spite of the fact that the Berlin physician is entitled to ask a higher fee than other German physicians on account of the higher cost of living in Berlin. A rule was laid down by the committee as one to be taken up in future conferences with the insurance officers, namely, that the better situated patient should pay more than the less fortunate one. The most equitable plan suggested is to pay the physician according to the amount of dues paid by the member. These dues vary with different societies from 27 to 60 marks per year.

It is advocated that in future the fund for the payment of physicians be kept distinct from that for the payment of other expenses, so that the fees paid to the physicians will not be affected by any unusual demands upon the treasury of the insurance offices. Strict regulation should establish the limit of income as 2500 marks at which individuals are eligible to membership in the insurance offices. It is a fact that at present many persons of means are members of the insurance offices and thereby save a considerable amount of money in their medical bills. Payment should be made for all certificates that do not pertain to the affairs of the insurance office. Provision should be made for the physicians' relief from duty on Sundays and holidays. The above represent only a few of the measures of reform that came up for discussion.

7. Spastic Paralytic Ileus. R. M. Green, F. S. Kellogg, and P. L. Harvie.

**1. Hand Lesions Following Injuries of Upper Extremities.**—C. H. Bucholz states that most cases of secondary posttraumatic lesions of the hand are seen following Colles' fracture. The clinical picture in such cases is rather typical: The forearm is somewhat flattened from the pressure of the splints. On the side of the forearm there is noticed more or less edema and often a distinct discoloration from an unabsorbed hematoma. The back of the hand and especially the fingers show, as the rule, a considerable swelling. The circulation of the hand is poor. On palpation one notices the infiltration about the tendons, especially on the palmar side of the wrist and forearm and on the back of the hand and fingers. There is often noticeable an infiltration about the interphalangeal joints. In all cases the hand and fingers are very weak, and in the vast majority considerable limitation of the motion of the fingers is noticed. With an increase in the clinical symptoms one notices the retraction and tightening of the fascia and tendons of the fingers and in bad cases, of the whole hand. The following may be considered as causes of the secondary traumatic hand: The primary injury, the hemorrhage, the forcible reduction of the fragments, the faulty application of splints and dressings, too long duration of fixation, and an ill-judged after treatment.

**2. Head Injuries of the Newborn.**—D. C. Wilcox states that in the majority of cases the autopsy shows the hemorrhagic centers to be in the parietal or frontal regions, close to the longitudinal sinus. The second most frequent center is just above or below the tentorium, or in the tentorium itself. When the parietal bones are made to overlap in an exaggerated manner, as they must do in a difficult forceps case, there is an extensive peeling off of the dura on one side, and of the periosteum on the other side. This allows a blood clot to form, which, if not extensive and conditions are favorable, will be absorbed without any ill effects; but if there be a continuation of the oozing, and the circulation be somewhat impeded, an intracranial local pressure will soon be exerted, which in time causes edema, with a resulting general pressure. Again, if there be an undue overlapping of the occipital bones, one upon the other, or of occipital upon temporal or parietal, there is quite likely to be a laceration of the tentorium. But while these tentorium lacerations are the most fatal, they are by no means the most unfortunate, for many of the frontal and parietal lacerations produce clots, which by their continued pressure tend to destroy the cells of the cortex, producing a porencephaly with all its attending mental defects.

**4. Fecal Form.**—F. L. Burnett notes that if the foul and formless stool be regarded as an indication of disease, this must be one that is very generally in existence, one that is also exceedingly insidious, and though varying a great deal in degree from time to time, must usually be rather protracted in its course. As a disease of the intestine, however, it would seem to affect the gastrointestinal tract primarily; but since a stool of this kind also implies an excessive amount of intestinal putrefaction and gives rise to an indirect toxemia, it seems likely, therefore, that it may cause degenerative or sclerotic changes in many tissues and organs. The cure or prevention of this disease is not accomplished by the use of an intestinal antiseptic or indeed of any other medicine, but simply by changing the habits of the individual, and using the form of the feces as a guide.

**7. Spastic Paralytic Ileus.**—R. M. Green, F. S. Kellogg and P. L. Harvie report two fatal cases of this condition. The cause of death was intestinal obstruction from a localized tonic contraction of the circular smooth muscle fibers of the small intestine, due to surgical trauma. Kelly and Noble describe the condition under the term dynamic or hyperdynamic ileus, and state that it constitutes 2 per cent. of all cases of intestinal obstruction. From the nature of its pathology, which is probably a mechanical injury to the plexuses of Auerbach and Meissner, the most convenient descriptive term for the condition seems to be spastic paralytic ileus. The lesson to be learned from the two cases reported by the author is the immense importance of avoiding all pinching trauma to the bowel during laparotomy. In the second case, this was perhaps inevitable, in the first it might easily have been prevented. The small intestine seems much more liable than the large to spastic paralysis. Hence in appendicectomy traction should *never* be made on the ileum for the purpose of bringing the cecum into the wound, but only the large intestine should be employed for such traction.

13. Beriberi. S. B. Doyle.

**4. Contraindications to Curetting.**—R. T. Frank states that the use of the curette is rarely necessary in abortion, is practically never necessary after labor, is harmful in pelvic inflammation, and is often fatal in ectopic gestation. Simple as the operation is in itself, it is a dangerous procedure unless controlled by careful limitations. The instrument is of value mainly for diagnostic purposes.

**5. Medical Treatment of Gastric Ulcer.**—E. E. Cornwall emphasizes the following points: Practically every case of gastric ulcer is entitled to at least one chance to recover without an operation, and most of the cases are entitled to more than one chance. The nonsurgical treatment of gastric ulcer consists essentially in keeping the ulcer as quiet as possible, which is best effected by rest in bed for at least four weeks, and a diet which will least irritate the ulcer and lease excite gastric peristalsis. Rectal feeding in the beginning is called for in all severe cases, and is desirable in the others. It may be kept up for a considerable period, especially if morphine is given in fairly large doses. The ulcer is least irritated by articles of food which are free from spices, condiments, acids, sugar, and indigestible residue, and which do not powerfully excite the secretion of the acid gastric juice. In other words, the ulcer is least irritated by a diet of modified milk and milk products, cereals, and bland fruits. Gastric peristalsis is least active if the food, in addition to being chemically unirritating, is fluid or semifluid, also if it is introduced in small quantities at a time. Speedy emptying of the stomach is facilitated by the patient lying on his right side as much as possible during the time that food is in his stomach. The return by the apparently recovered patient to ordinary diet should be very

gradual; especially moderate for a long time should be his indulgence in food that is slow of digestion, of sweets, and of animal food which stimulates strongly the secretion of acid gastric juice. Olive oil is soothing to the ulcerated stomach, is good food, and is laxative. Drugs, as such, are of very little use in the nonsurgical treatment of gastric ulcer.

6. **The Blood in Pulmonary Tuberculosis.**—C. Rayevsky states that the blood pictures obtained by the various counts reflect a great deal the processes going on in the body during disease, and in pulmonary tuberculosis they show the negative and positive phases quite as well, and in the author's opinion much better than the opsonic index; they show more elements in the blood that are of importance than the opsonic index does.

8. **Convalescing Children.**—LeG. Kerr believes that in the treatment of convalescing children in order that one may bring about a normal return to full efficiency, there should be coupled with the measures used to restore physical efficiency, such instruction, training, and well guided amusement and play as will occupy the child's increasing mental and moral powers in a measure commensurate with its increasing strength. In the home this can usually be accomplished by the careful parent, if he or she is properly instructed and the child is safeguarded against fatigue. The safest method is to use old toys, old books, and familiar things in both instruction and play, because the new always tends to excite the child, and, as inhibitory control is weakened by illness, no undue excitation is justified. In institutions, particularly in hospitals that have any considerable number of children as patients, there should be added to the hospital force a trained kindergartner or at least some one who is sufficiently trained to stimulate and guide the increasing powers for mental and moral development.

11. **The Blood Catalase in Malignant Tumors.**—G. L. Rohdenburg does not believe that the determination of catalase activity is of any diagnostic value in cases of malignant tumor. A high catalase activity occurs in conditions other than malignant tumors. Winternitz noted its occurrence in peritonitis, and it occurred in cases of acute articular rheumatism, bronchiectasis, and cerebral arteriosclerosis. A normal index is of little value; a depressed index occurs in other conditions, notably nephritis. The exact significance of the inhibition of enzyme activity, both proteolytic and catalytic, is far from clear; it is not a change distinctive of cancer alone. That inhibition is due to the formation of antibodies is at the present not proved.

2. **Systematic Exercises in Postoperative Treatment.**—E. H. Pool states that while it is impossible to estimate accurately the effects of postoperative exercises, their trial in a number of cases seems to support the theory that as a result of their use the general circulation is improved, the functions of the body are performed in a more normal manner, the patients feel better, muscular weakness and atrophy are diminished, and after getting up exertion is less fatiguing and return to normal is more rapid. The two objections—possible interference with the repair of the wound and danger of embolism and thrombosis—may be disregarded. No injury to the wound is to be anticipated provided proper exercises are selected and intelligent instruction is given the patient; moreover, there is no valid reason to fear embolism and thrombosis; in fact, there is some reason to believe that the exercises may be advantageous as a prophylactic against these complications. If postoperative exercises are desirable, it is essential that their use should be systematized. A general policy may be adopted in each variety of operation as to the kind of exercises, the number of times each is to be performed, the number of times a group of exercises is to be carried out each day, and definite times for their performance. Yet in many cases the condition of the patient and the nature of the operation demand variation from a fixed routine, so that, although a definite plan may be followed in general, supervision is essential in every case.

5. **Complement-Fixation Tests in Arthritis Deformans.**—T. W. Hastings records the result of his investigations as follows: Of the typical cases of arthritis deformans, of from two to fifteen years' duration, six reacted to strains of *Streptococcus viridans*. From four of these cases the same organism was isolated from a tooth-socket after the extraction of teeth—in three of the four, complement-fixation tests were found positive before the infection of the alveolar processes was looked for. One of these cases reacted to the gonococcus also. Four cases of typical arthritis deformans reacted to the gonococcus; one of them to streptococcus also. Three cases, which were classed from the history as infective deforming arthritis, reacted to the gonococcus. The deformities were typical of arthritis deformans. In twelve cases of typical arthritis deformans the tests were negative for the Wassermann reaction, and for the gonococcus, the streptococcus and staphylococcus. Improvement under treatment with injections of vaccine, considered specific on account of the complement-fixation tests, has strengthened the supposition that some cases of arthritis deformans are infective in nature and that the infecting germ may be a *Streptococcus viridans* or a gonococcus.

11. **Variola and Vaccinia.**—P. M. Ashburn offers the following explanation of the relationship of variola and vaccina. The germ of smallpox by passage through certain lower animals loses (acquires) certain properties, and transmits its altered condition to its offspring forever. Smallpox is due to a dual and divisible virus, one part of which causes vaccinia and the specific smallpox eruption, the other part being necessary for the production of the contagious, generalized, mortal disease with a distinct preeruptive stage and initial rashes. As evidence favoring this explanation he cites examples of other viruses which seem to show a similar duality and animal poxes and variolation of animals. The three forms of smallpox not showing a pock stage, or only an incomplete one, purpura variolosa, varioloid and variola sine exanthemate, occur in vaccinated persons as often as, or more often than, in unvaccinated. Vaccinia therefore protects against the pox stage of smallpox rather than, or to a greater degree than, against the whole disease. Twenty-two per cent. of 2,601 persons who had had variola or been variolated were still susceptible to vaccinia, though immune to smallpox.

14. **Traumatic Subdeltoid Bursitis.**—J. M. Flint discusses the traumatic bursitis of the shoulder joint which has been heretofore treated in its acute stage by immobil-

izing the joint to prevent further traumatism. The method of treatment which he suggests is aspiration of the joint. This method was first used by him in a case of metastatic bursitis in empyema from acute osteomyelitis of the femur. Aspiration of the bursa yielded pus and the diagnosis was confirmed by operation. Two cases of subdeltoid bursitis following injury are reported in which aspiration afforded complete and prompt relief. In the promptness of its results the effect of the aspiration can be compared only to that obtained in a case of a ganglion or weeping sinew. There may have been more severe cases, in which frequently more repeated aspiration would be required and it is particularly desirable to know how the method would apply to chronic cases. A Luer syringe is partly filled with about 1 c.c. of sterile cocaine or novocaine solution. The latter is injected into the skin and ahead of the needle as it passes through the deltoid. The needle is pointed roughly parallel to the clavicle and directed toward the bursa lying just over the bicipital groove. The point of entrance is about 2 cm. below the level of the acromion process. As the point of the maximum tenderness lies directly over the bursa, this will prove perhaps the best guide for the needle for it is just at this point that fluid was obtained in the author's cases. After the aspiration, it may be well to fix the joint in a Velpeau bandage for a few days.

**2. Peripheral Vasoconstriction and Mouse Cancers.**—C. Walker and H. Whittingham studied the effect of injections of extract of ergot or pituitary body upon mouse cancers. They found that these two substances produced somewhat similar results to the substances used by Wassermann and by Neuberg and his collaborators. In the case of the pituitary extract, where the dose was larger and more injections were given, necrosis was induced as well as hemorrhages, and the growth of the tumor was apparently checked in a large proportion of cases. The mechanical explanation appears to explain the action of the extract of ergot and of the pituitary extract, and there is no suggestion that there was any specific action upon the cancer cells. It seems possible that something might be done towards producing an effect upon cancer cells by injecting substances which will tend to kill the cells, in combination with something which will contract the blood-vessels of the body, such as pituitary extract and extract of ergot. The passive dilatation of the vessels in the tumor should collect the toxic substance there, though, of course, it will be diffused over the whole body to a less extent. There is no evidence that Wassermann's or any of the other substances used have any specific action upon cancer cells, as the contraction of all the blood-vessels excepting those in the tumors accounts for all the results that have been obtained.

**3. Treatment of Large Herniæ.**—A. E. Barker has found in almost every case that Bassini's operation carried out with every attention to detail is quite adequate for all inguinal herniæ, great and small. In some cases where the tissues are very slack the modification of overlapping the edges of the rings described by Halsted will be found to give a thicker scar than that formed by merely drawing the edges together. The large sac need not be dissected formally out of the scrotum. At its neck, of course, it must be separated and for some little distance. To do more is to risk considerable oozing into the areolar tissue of the scrotum and a troublesome hematoma. An exception to leaving the sac intact in the scrotum is when the contents are almost universally adherent. Then it should be removed with the attached omentum. When this is separated at the neck and well drawn down it is tied off and cut across, the lower part of the sac when adherent to the omentum being taken away with it, or if non-adherent left open, as much of it being removed as was separated below the neck. It must not be forgotten that when the veins of the cord are pressed upon by the reduced rings an engorgement of the veins of the scrotum follows which favors oozing, so that all small and large bleeding points should be attended to before the wound is closed. If, in spite of this, there is still a tendency to ooze, a drain should be introduced for 24 hours, as a hematoma in this region may be troublesome. After 24 hours the drain will probably do no good, and may even form a track for the infection of the part from without. The possibility of septic matter lurking in the folds of the scrotal skin and its hair, sebaceous and sweat follicles, must always be borne in mind. Unless great care has previously been taken in the daily preparation of the scrotum to encourage these glands to act freely and carry any hidden bacteria to the surface, the danger of infection during or after operation is considerable. Frequent washings with soft soap and water as hot as can be tolerated are called for, followed before operation by the iodine solution. But the latter must be used with caution, as it produces eczema in some cases. As to the use of silver filigrees inserted deeply in inguinal herniæ to add strength to the abdominal wall, the author believes that in the large majority of cases they are unnecessary.

**4. Polycythemia.**—T. K. Monro and J. H. Teacher state that true polycythemia may be either symptomatic or primary. Symptomatic or secondary polycythemia is an erythrocytosis, analogous to a leucocytosis. It is met with in cases of chronic cyanosis associated with heart or lung disease, and it is also found in man and other animals living at high altitudes. This erythrocytosis is compensatory in its nature, and is attributable to stimulation of the bone marrow by the deficiency of oxygen. Primary polycythemia or erythremia is analogous to leucemia, there being no obvious reason why the bone marrow should show the excessive erythroblastic activity. It is known by a variety of names, including "Vaquez's disease," "Osler's disease," "splenomegalic polycythemia," "myelopathic polycythemia," "polycythemia with chronic cyanosis," and "erythrocytosis megalosplenica." These titles, however, are not all suitable, since cyanosis is absent in some cases, while in other cases there is little or no splenic enlargement. Whether the syndrome represents a single morbid entity, a disease *sui generis*, may be more definitely ascertained when a greater wealth of pathological and clinical material has accumulated, and the degree of affinity between the different types can be more precisely determined. The symptoms in the initial stage may be of a vague as well as varied character, and it is probable that the disorder of the blood may exist for a considerable time before it causes any grave or manifest disturbance of the general health. It is further probable that the disease would be found to be more common than is generally recognized if an examination of the blood were a more constant routine of clinical work.

7. The Nascent Iodine Treatment of Lupus Nasi. P. W. Bedford.

1. **Rheumatoid Arthritis.**—Sir James Barr believes that the proximate cause of this condition is a mild chronic acidosis which extracts the lime salts from the fibrous tissue, muscles, nerves, cartilages and bones. He regards this affection as a general disease, and the apparent localization in the joints as due to their structure and liability to injury. The extraction of the lime salts from the fibrous tissue causes it to swell and its vascularity to increase; with the loss of the lime salts the muscles get into a condition of irritable weakness—they waste, readily contract, cramp frequently occurs, all the deep reflexes are exaggerated, and even a state of rhythmic tremor may be set up. There is not much lime in the nervous tissue, but its abstraction leads to a marked result; neuralgic pains readily occur, and even neuritis is easily established.

2. **Fibrositis.**—A. P. Luff points out that the essential pathological change in fibrositis is an inflammatory hyperplasia of the white fibrous tissue in various parts of the body, associated with exudation and proliferation of the connective tissue elements leading to swelling and thickening of the affected fibrous tissues. This condition may undergo absorption and so completely disappear, or, if not suitably treated, it may pass on to organization with the formation of nodules and patches of thickening. The white fibrous tissues in practically any part of the body may be affected, but the liability is greater in certain situations. Muscular rheumatism is always a fibrositis. Any of the muscles may be affected. Affection of the muscles of the lumbar region constitutes one of the forms of lumbago; affection of the muscles of the neck constitutes stiff-neck; affection of the deltoid muscle constitutes "deltoid rheumatism," etc. Dupuytren's contraction is a localized fibrositis caused by habitual postural use of the hand. A fairly common form of localized fibrositis is that which affects the plantar fascia. This causes pain in the sole of the foot when the weight of the body is on it, and if not arrested is liable to lead to the development of flat-foot. A chronic fibrositis of bursæ is fairly common, and especially occurs in connection with the subacromial bursa. Chronic fibrositis of the joints is most frequently met with in the knuckle-joints and finger-joints of those engaged in hard manual labor, especially when associated with damp surroundings. A form of fibrositis to which Stockman has recently drawn attention is a chronic subcutaneous fibrosis, which when it occurs in people with a large amount of subcutaneous fat is apparently identical with the disease known as "adiposis dolorosa."

3. **Types of Organism in Bone and Joint Tuberculosis.**—J. Fraser presents the following conclusions: (1) It is possible by certain tests to distinguish between human and bovine types of tubercle bacilli. (2) A considerable proportion of bone and joint tuberculosis of children in Edinburgh is due to infection by the bovine bacillus. (3) The bovine bacillus is introduced into the body by the drinking of infected milk. (4) A considerable proportion of the cases of tuberculosis due to the human bacillus are the result of the direct infection of the child by a consumptive co-resident.

6. **Penetrating Wounds of the Heart.**—E. de Verteuil reports two cases of penetrating wounds of the heart, which were operated upon. In one of the patients the operation was successful. In the light of his experience the author puts forward the following conclusions and suggestions: A great many cases of penetrating wounds of the heart might easily escape recognition if too much reliance be placed on the failure of the probe to enter the thoracic cavity; but when it is borne in mind that a stab wound (made often with the thin blade of a knife) in that position usually has to traverse several layers of muscles, the fibers of which run in various directions, it can easily be conceived how difficult it would be to detect the opening into the chest by means of a probe. All such wounds in the vicinity of the heart which give rise to symptoms of shock and collapse (even in the absence of other signs, such as an increase of the area of cardiac dullness, etc.) should be immediately enlarged and the thoracic walls sufficiently exposed for a thorough examination for a possible wound of entry, which, if found, would necessitate an immediate operation. It is not usually known that the proportion of recoveries among the 124 cases recorded of operations of suture of the heart after injury is as high as 40 per cent. As to the use of ordinary catgut in suturing wounds in the heart, the author is quite certain that catgut is unsafe, as it is too elastic and does not hold sufficiently long to insure firm union between the edges of a muscle which is continually contracting and retracting. Iodized or chronic catgut, however, which lasts a great deal longer, may be used with safety, but the author prefers, and can see no reasonable objection to, the use of thin silk applied not too tightly. The selection of the ribs to be removed seems to me also an important consideration Complete exposure of the pericardium and heart can easily be obtained by removing the fourth and fifth costal cartilages—instead of the fifth and sixth, or fourth, fifth, and sixth as recommended by some—thus leaving the sixth rib in position as a support to the heart when the patient is in the erect position. Most writers lay much stress on the necessity of trying to avoid opening the pleural cavity—no doubt for fear of causing a pneumothorax. In both the author's cases the pleural cavity was opened and a pneumothorax caused, and in spite of their very grave condition at the time of operation, the patient's symptoms were not aggravated by this procedure. As regards the after-treatment, in addition to the usual treatment for hemorrhage, an ice-bag kept over the heart continuously and hypodermics of morphine are extremely useful adjuncts for rallying the distress and pain. Complete rest in bed for at least three weeks after the injury must be thoroughly enforced for fear of embolism.

## Berliner klinische Wochenschrift.

*April 7, 1913.*

**Warfare Against Malaria in Jerusalem.**—Brünn and Goldberg, the authors, are in charge of the Health Bureau of the Jewish Agricultural Experimental Station, founded by Nathan Straus of New York. This is intended to combat the endemic diseases and especially malaria. Two thousand blood examinations have been made, and the spleen and liver have been investigated in 600 subjects. In 21.5 per cent. there were malarial finds in the blood, while in over one-half of the visceral examinations the spleen was found altered. It is readily apparent that the prophylactic problem is bound up in the large number of cisterns or reservoirs present in the city, which serve as breeding places for the anopheles. In the absence of an aqueduct system, the only available resource is to protect the cisterns, for it is self-evident that nothing can be added to the drinking water itself. The openings from which the water is dipped are not the only means of access available to the mosquitoes. The rain water is conveyed to the cisterns by means of grooves and spouts, and it is possible for the insects to fly through the latter. The main pipe may therefore be provided with a trap which opens only during the rain. Other devices for rendering the cisterns mosquito proof are being installed. Thus far

200 of the reservoirs have been thus treated. Naturally it is much too soon for decisive results, and in fact the subject is decidedly in the experimental stage, for it may not come about that the cistern campaign will in itself dispose of the mosquito outright. Other measures are being used collectively (fumigation, petroleum, quinine).

**Fowl Sarcoma and Its Filtrable Virus.**—Rous and Murphy of the Rockefeller Institute, who have written many articles on this subject, conclude their present study as follows: They have already acquired more than a suggestion as to the cause of malignant tumors. The author's finds give a rational explanation founded on facts of certain of the mysterious characteristics of the latter. The peculiarities of their origin, the significance of cell destruction by other cells for their etiology, growth and distribution, the behavior when transplanted are all in accord with the supposition that an agency is concerned, the activity of which may be inhibited by various conditions which have something in common with the cause of fowl tumor. The causal nexus, however, is probably complicated in its nature. In any event the theoretical objections to the external origin of cancer have been strongly affected by the finds in fowl sarcoma.

**Etiology of Hydrophobia.**—Proescher of Pittsburgh sums up his studies of rabies virus as follows: Clinical and experimental studies alike show the probability that the cause of rabies may exist in a mobile form. It is known that the virus migrates exclusively along the nerve paths and that this movement cannot be passive. One therefore thinks at once of spirochetes. It is probable from analogy that during the stage of repose of the spirochete cocci are formed which may be able to give rise to further spirochetes. Cocci which correspond in part to these are found in abundance in the antiformin sediment of the salivary glands. The apparent incongruity of these finds may be explained by the recent claim that spirochetes must henceforth be classed as bacteria. The question can readily be settled should attempts to cultivate these cocci and cause animal rabies be successful.

*March 27, 1913.*

**The New Remedies of the Past Year.**—Biberfeld states that the accessories of 1912 were not numerous, which is in some respects a healthy sign. With fewer remedies more time may be devoted to the study of each. He regards the work on opium derivatives as the most valuable. Morphine is still the most important of these. It is claimed that narcotin, long regarded as inert *per se*, is useful for modifying the action of morphine. A mixture of narcotin with meconate of morphine has been placed on the market under a proprietary name. It contains 30 per cent. of the alkaloidal morphine and is used in a threefold dose. Morphine has further been associated with its antagonist thebain and other opium alkaloids in proprietaries in the form of solutions. These contain 1 per cent. morphine and smaller proportions of thebain, codeine, narcotin, papaverin, and narcein. The mixture, therefore, combines morphine with both synergists and antagonists. Synergism is also sought in combining veronal with codeine as a hypnotic and with quinine as an antitussive in pertussis. Several synthetics closely related to veronal are being widely advertised as competing hypnotics. New combinations of bromine are still being introduced, one of the latest containing borneol. There has been unusual activity in devising new antiseptics, at some of which the author looks askance and none of which seems to have attained much vogue. The individual find of the year irrespective of class is doubtless neosalvarsan.

**Serological Investigations in Lepers.**—Möllers sums up the results of his work at the Koch Institute (Berlin) as follows: The serum from patients with tuberous or mixed leprosy gave a complement forming reaction in tuberculin in from 95 per cent. to 100 per cent. On the other hand anesthetic or nervous lepers reacted thereto only to the extent of 25 per cent. In the blood serum of lepers there was more pronounced autibody formation with bacillary emulsion than with culture fluid preparations. The pressure of these tuberculous antibodies in leper blood does not justify the conclusion that such lepers are actually tuberculous as well. The clinical significance of the phenomenon thus far is that reaction to tuberculosis is a measure of the severity of the leprous infection.

**The Appendix in Röntgen Pictures.**—Cohn states that what we know in this field is the result of accident despite the intense desire and continual efforts of years in this direction. A Russian physician, Grigorieff, chanced to be the possessor of a retina extremely sensitive to *x*-ray shadows. After years of observation and using his so-called trochoscope he announced that the appendix had a proper motion and that it rhythmically filled and emptied itself. The author has been able to witness this phenomenon himself. In order to apply the method the patient is given the usual bismuth test meal and repeated flashlight negatives taken. The technique is very complicated, that of the author differing notably from Grigorieff's. His conclusions are as follows: The appendix may be studied with *x*-rays in the majority of cases. The investigation is a methodical one. While it is a part of a routine examination of the intestines it also holds a special position *per se*. We seek to determine the site and mobility of the organ as well as its special physiological function. The appendix is not filled synchronously with the passage of chyme from the ileum into the colon. It is, therefore, probable that retrograde movements of the colon are the principal factor in the filling of the appendix. When the latter cannot be emptied stagnation comes about. Shadows are visible at times in the appendix long after the colon is seen to be empty.

**Intraperitoneal Application of Oil.**—Momburg, on a basis of personal experience, would warn others from further application of oil in the peritoneal cavity. Oil injections in every kind of application are prejudicially to the organism, and in weakened individuals may exert a critical action. The good results are problematical and cannot offset the injury done. The author would anoint the site of the incision in order to guard against possible soiling by stomach or intestinal contents. In order to prevent postoperative peritonitis we have other and safer resources, such as the hot-air chest.—*Deutsche medizinische Wochenschrift.*

**A Serous Cyst Evacuated from the Ramus of the Mandible.**—L. H. McGavin reports the case of a man, aged thirty, in whom three years ago a swelling developed in the left parotid region; as it steadily increased in size it was incised. Nothing but blood was evacuated. The swelling was not painful and after operation again increased in size. On examination the tumor was about the size of a tangerine, it was firm in consistency, and evidently deep to the masseter muscle. There was no facial paresis, although the tumor lay in the line of the facial nerve. In the center fluctuation could be felt; no bone cracking was detected. All the teeth of upper jaw except the wisdom tooth were present; this latter had been removed a year previously. Under chloroform an incision, following the angle of the jaw, was made, and a flap containing the masseter was turned up. The mass proved to be a cyst in the upper part of the ramus of the jaw, which was expanded to a thin shell, and contained clear yellow serous fluid. The lining membrane was removed. Microscopical examination gave no indication as to the nature of the cyst.—*Proceedings of the Royal Society of Medicine.*

## Insurance Medicine.

**The Local Medical Examiner and Life Insurance.**—In a paper read before the Ottawa Valley Medical Association, B. G. Connolly tells of the position occupied by the local medical examiner in life insurance work. Life insurance, not only through great companies, but through fraternal societies, has assumed a tremendous importance in the economy of the life of today. The success of all insurance companies depends on three factors: Wise medical selection, charging of proper premiums, and honest, prudent management. The medical department is the one considered here. The medical examination is the foundation stone of insurance work, and on the honesty, integrity, and proficiency of the examiner depends, in a great measure, the success or failure of a company. How can the medical examiner most satisfactorily discharge the service expected of him is a pertinent question. He, through his examinations of the applicants, represents the company, and he is bound to give to the company an exact picture of the physical condition of the applicant as he finds him, and on that picture depends the acceptance or rejection of the applicant by the company. Insurance companies furnish forms consisting of two parts and containing a number of questions, the intelligent replies to which are the means by which the head office judges of the eligibility of the applicant for insurance. Part I. is filled out by the applicant and relates to his past history and family history. Part II. is filled out by the medical examiner and answers all questions relating to the present condition of the applicant. If all questions are answered satisfactorily, the medical examiner's work is done; but often the replies to the first part of the report are vague or incorrect. The second part is rarely questioned. An applicant may profess vague knowledge of his family history, or his own early life. A certain mental bias, usually unconscious, obtains in answering these questions by the applicant, as he desires a favorable decision and thus colors his statements. Here is where the tact and intelligence of the medical examiner are required, for by patience he can elicit correct answers, saving delay not only for himself, but for the agent and the applicant. In the preparation of his report, the medical examiner has two powerful aides, the sphygmomanometer and urine analysis. The importance of blood pressure has long been recognized and by the use of the sphygmomanometer it can be accurately registered. Certain companies make its use obligatory where the applicant is over 40 years of age, and when the reading shows the pressure to register over 150 mm. of mercury, the applicant is rejected, it being believed that the high pressure is a forerunner of albuminuria or apoplexy in a few years. The importance of correct urine analysis is so generally understood that it is scarcely necessary to refer to it. —*Canadian Practitioner*, December, 1912.

**Medical Considerations in Insurance.**—Dr. Böhler says that the insurance examiner is not interested as much in knowing *how many* men die at fifty or at sixty, of pneumonia or of any other disease, but *which* men die at such and such an age, and of such and such a disease. People do not usually die of an affection because it is very severe, but because their resistance has become diminished in one way or another, and it is this diminution of resistance that must be judged by the examiner. The following factors enter in such a judgment: heredity of the applicant, past life, dangers of future occupation, his apparent power of resistance at time of application, etc.

Heredity may mean inheritance of disease (e.g. syphilis) or simply of predisposition (e.g. tuberculosis). Obesity, diabetes, gout, arteriosclerosis are frequently supposed to show a predisposing moment due to heredity. Hemophilia is strictly an inherited disease. Mental disturbances frequently run in families. Mental worries, business troubles, etc., must be considered in estimating the effects of past life. Syphilis or tuberculosis in the past, though apparently cured, should from the insurance standpoint always lead to the classification of the applicant as a substandard risk.

In estimating the future risks in applicant's life, the nature of his occupation should be considered: miners, bakers, metal workers, liquor dealers, all show a higher mortality than the average. If some hereditary predisposition is present in such applicants, they become substandard risks. Thus, a baker with a family history of tuberculosis runs a grave chance of dying from this disease. Syphilis must be especially carefully kept in mind; even though modern methods of treatment have shortened its early manifestations, we know that the vascular system may be early affected by the disease and lead to premature senility.

Of late, the special risks of tropical sojourn have become an actual problem in insurance, for it must be granted that, however healthy he may be on arrival, almost every European finally is affected by the tropical climate. Estimation of each individual risk is of importance in these applicants more than in any other class.

Modern insurance methods have changed the estimation of applicants a great deal by the introduction of term insurance. The frequent problem for the examiner is, nowadays, not how long will an applicant probably live, but whether he will live the number of years to the conclusion of his term of insurance, and especially whether there is any probability of his dying within a short time after insurance has been effected.—*Zeitschrift für die gesammte Versicherungs-Wissenschaft*, Band XIII, Heft 1.

**Early Life Insurance.**—In an article, entitled "Notes on Life Insurance Examinations," William J. Stapleton, Jr., gives a brief history of life insurance. Life insurance, as we know it, is an offshoot of marine insurance. In the early days, the success or failure of a voyage depended largely on the personal qualities of the master; the owners of the ship and cargo took out insurance on the master so that in the event of his death they would be recompensed. The earliest known policy was taken out on the life of one William Gybbon in London, the year 1583. The earliest life insurance company of which we have definite information was the Mercer's Company of London, established in 1699. The first company in the United States was founded in Philadelphia, in 1758, and was called the Presbyterian Annuity and Life Insurance Company. Until 1840, there was little business done; during the next ten years, up to 1850, several of the companies now doing business were organized, namely, the Mutual Life of New York in 1842, the New York Life in 1845, and others. Now there are several hundred companies organized to transact the various kinds of insurance business.—*Journal of the Michigan State Medical Society*, April, 1913.

# Book Reviews.

A Text Book of Obstetrics. By Barton Cooke Hirst, M.D., Professor of Obstetrics in the University of Pennsylvania; Gynecologist to the Howard, the Orthopedic, and the Philadelphia Hospitals, etc. Seventh edition, revised and enlarged, with 895 illustrations, 53 of them in colors. Price, $5.00. Philadelphia and London: W. B. Saunders Company, 1912.

In the seventh edition of this work a more logical arrangement has been adopted, the physiology of the process of generation preceding the pathology. As in former editions the diseases of women and their treatment are included. The article on the "Diseases of the Breast" has been extended. The section devoted to operative technique is well written and the steps of the various operations are thoroughly illustrated. A considerable part of this section is devoted to gynecological operations, such as the repair of the cervix and perineum, hysterectomy, salpingo-oöphorectomy, and operations for retrodisplacements of the uterus. Short articles on breast operations and the after-treatment of abdominal operations are included. The book has been well brought up to date. Many new illustrations have been added. Some of the old ones have been discarded, while others have been modified. Dr. Hirst has maintained the high standard of the former editions, and his book remains valuable and of service to both the medical student and the man in active practice.

Experimental Physiology. By E. A. Schäfer, F.R.S., Professor of Physiology in Edinburgh. Price $1.35 net. London, New York, Bombay, and Calcutta; Longmans, Green, & Co., 1912.

This volume is an outgrowth of the author's handbook for classwork in Practical Physiology which has been enlarged and furnished with new illustrations. A large part of the text is given over to the description of apparatus and the directions for the performance of experiments are very condensed. With the exception of two pages devoted to secretions, practically all the work is designed for frogs. For this reason many of the exercises by which the respiration, circulation, etc., are investigated in mammals, are entirely omitted. This fault renders the book rather incomplete for the use of the American schools and in fact it seems more particularly intended for courses given under the restrictions which are in force in Great Britain to-day.

Starving America. By Alfred W. McCann, Member of Vigilance Committee, and Associated Advertising Clubs of America. Price $1.50 net. Cleveland and New York: F. M. Barton, 1913.

As a chemist, as manager of a large department store having a grocery department, and later of a large food industry, Mr. McCann came in contact with food inspectors, chemists of the National and State departments, food manufacturers, importers, jobbers, and commission men. He is thus in a position to know the inside and his book is an exposé of food deficiencies and adulterations. He is a great advocate of whole grain foods and believes that the mineral constituents of foods have not been duly appreciated. Our white flour and prepared cereals are robbed of their mineral constituents and this deficiency together with the adulteration of other food stuffs he believes to be indirectly responsible for many of the deaths of infants and children and for the large number of undernourished and defective children and tuberculous, anemic, and neurasthenic adults. One chapter, devoted to the presentation of facts concerning the sixteen principal elements found in natural food, is written specially for the physician. The book will undoubtedly be instrumental in awakening a wider popular interest as to the need of better pure food laws and their more drastic enforcement.

The Illness and Death of Napoleon Bonaparte (a Medical Criticism). By Arnold Chaplin, M.D., (Cantab.), Fellow of the Royal College of Physicians. With three illustrations. Price 70 cents. London: Hirschfeld Brothers, Limited, 1913.

The author of this little volume is justified in adding to the already voluminous Napoleonic literature by the fact that an account of the last illness and death of Napoleon has not thus far been written which is not lacking in accuracy and proportion, probably because the historian rarely possessed the equipment necessary for dealing with a complicated medical problem. The account of the last illness and death of Napoleon, as related by Dr. Chaplin, is based on the "Lowe Papers" in the British Museum. He compares three different accounts of the post-mortem examination as written by three of the physicians present on that occasion and concludes that Napoleon died of cancer of the stomach which most likely originated in a chronic ulcer and remained undiagnosed until the post mortem was made. Of the medical men who attended Napoleon not one had any correct idea of the true nature of the disease, and, furthermore, political bias of necessity divided them into two opposite camps and obscured the issue. The author shows what he considers conclusive evidence that Napoleon was not epileptic, as has generally been supposed. Short biographies of the attending physicians and an account of the exhumation of the body in 1840 are also included.

The Child. By The Hope Farm Man. New York: The Rural Publishing Company, 1912.

This story has no plot that can recommend it as a romance, but is merely a record of everyday events in a poor farming community of the "hill country." A childless couple take a very unpromising waif into their home who brings something of the truth and faith and joy of childhood into their narrow and unsatisfied lives. The author makes this incident serve to show that a home, even a humble one, is much better for the dependent child than institutional life, and how a rural community impoverished by the middleman may be awakened to the advantages of organization and the spirit of fraternity. The spirit and the thought of the book will appeal to those who find pleasure in the simple things of life and to those who are interested in the problems presented. The story possesses more literary merit than the modest author would have us believe.

Obstetrics: a Text Book for the Use of Students and Practitioners. By J. Whitridge Williams, Professor of Obstetrics, Johns Hopkins University; Obstetrician-in-Chief to the Johns Hopkins Hospital; Gynecologist to the Union Protestant Infirmary, Baltimore, Md. Third enlarged and revised edition. With 16 plates and 668 illustrations in the text. New York and London: D. Appleton & Company, 1912.

It is a pleasure to review a book such as this, which combines many excellent features in its literary, scientific, artistic and mechanical details. There can be no question that Williams' "Obstetrics" ranks among the best. The present edition represents a thorough revision, the most important changes being found in the chapters upon the development of the ovum, the organic changes incident to pregnancy, pubiotomy, and cesarean section, pernicious vomiting of pregnancy, and the frequency of contracted pelvis and the treatment of labor complicated by it. The author alludes to the value of rectal examination in the prophylaxis of puerperal infection, this method of examination enabling one to determine the degree of dilatation of the cervix and the position of the presenting part in the pelvis. Curettage as a routine procedure in the treatment of puerperal endometritis is strongly condemned. No good results have been observed by the author in the treatment of streptococcic puerperal infections by mean of vaccines, but it is stated that Polak is more optimistic as to their use. The numerous illustrations, including the colored plates, cannot be excelled for their cleanness, didactic value, and artistic merit. The bibliographical references at the end of each chapter are particularly serviceable.

Beitrag zur Beurteilung und Behandlung des konkomitierenden Schielens. Von Gustav Caesar in Marburg a. d. Lahn. Price 1.50 M. Halle a. S.; Carl Marhold Verlagsbuchandlung, 1912.

This monograph of 43 pages present a careful study of a large number of cases of concomitant strabismus that have come under the observation of the author. The cause and influence of heredity on strabismus are discussed. The results of operative and non-operative treatment are given and the various forms of procedure described. The monograph is carefully prepared and is well worthy of studious perusal by those who are interested in this branch of ophthalmology.

Sehproben-Tafeln. Von Prof Dr. Berthold Kern, Obergeneralartz, und Dr. Reinhold Scholz, Generaloberartz. Dritte verbesserte Auflage. Price 3 M. Berlin: Verlag von August Hirschwald, 1913.

This work consists of charts of block letters and unfinished block numerals, so arranged that the patient cannot readily memorize them, with the equivalents of visual acuity indicated. Charts for mirror use, as well as the ordinary distance charts, are supplied. The letters do not follow the law enunciated by Snellen, the bars being wider than the spaces. The letters are selected in regard to uniformity. The popularity of the charts is attested by the fact that the work is in its third edition. An explanatory pamphlet accompanies the charts.

# Society Reports.

## MEDICAL SOCIETY OF THE STATE OF NEW YORK.

*One Hundred and Seventh Annual Meeting, Held in Rochester, April 29, 30 and May 1, 1913.*

(Special Report to the MEDICAL RECORD.)

HOUSE OF DELEGATES.

THE PRESIDENT, DR. JOHN F. W. WHITBECK OF ROCHESTER, IN THE CHAIR.

**Report of the President.**—Dr. JOHN F. W. WHITBECK of Rochester presented this report. He reminded the Society that his predecessor had made several valuable recommendations which should be wisely discussed by the House of Delegates as a whole or by duly appointed committees. Committee work was desirable and decidedly advantageous and he, therefore, urged the appointment to the House of Delegates of a committee for each specific purpose of sufficient importance to require extended investigation and tests of expediency and presentation to those who had the authority to act, either in legislative or executive capacity. Owing to the magnitude of the interests of the State of New York in its financial and populous importance, it did not seem unreasonable that, situated as it was, it should essay to exert a potent influence upon the acts of Congress in many, if not all, of the great and vital affairs of the whole people of the nation. If the federal Government could be persuaded that the highest interests of 90,000,000 inhabitants of the United States demanded an organization of a veritable National Department of Health, there would be a Secretary of Health, whose undivided attention, divested of pernicious policies, would definitely provide for a needful and efficient regulation of Pure Food and Pure Drug Laws, a Division of Purification of Water Supplies, a Division of Nutrition, a Division for the Study and Prevention of Accidents and Diseases of Industrial Workers, a Division of Vital Statistics, and a Division of Education for the People in the Control and Prevention of Diseases. Then, too, there should be a National Chemical Laboratory to solve many of the vexed problems of national importance. All of these divisions should come under one department and would be under the supervision of one secretary, and not scattered among several departments, making the highest efficiency impossible. For a review of this proposition the members were referred to the article by Earl Mayo published in the *Outlook*, December 7, 1912, p. 764. The President recommended that the consideration of the New York Industrial Diseases Reporting Law be referred to the Committee on Lgislation. It was to be questioned whether there had come to be a proper appreciation of the relation of disease to industry. It was certainly important that diseases of occupation should receive the most careful attention and investigation. As President, he urged that the House of Delegates take some decided step in this matter, and if deemed advisable, appoint a special Committee on Legislation as well as to second the action taken by the Committee of the American Medical Association. After referring to the organization of the five sections, the President emphasized the importance of general discussion of the scientific papers, which hitherto had been often wanting or insufficient and unsatisfactory. It was believed that the arrangement of the five sections, as now constituted, would prove to be satisfactory, and it was doubtful if the State Society could afford to spare one of the scientific sections as at present organized. If positively advisable, other divisions might be incorporated into the existing sections without radically changing those on trial, by simply extending the scope of their usefulness. The total attendance at the last meeting was 721 members. The presidents of the District branches had been urged to stimulate increased membership and every County Society president had been repeatedly importuned to secure new members and larger attendance for the respective county conventions. The chairmen of the sections and the Committee on Scientific Work had been especially active and their efforts were deserving of the highest praise for what bid fair to be the unqualified success of the 107th annual meeting of the Medical Society of the State of New York.

**Report of the Secretary.**—Dr. WISNER R. TOWNSEND of New York submitted this report, which showed that the membership of the Society on January 1, 1913, was 6,964, an increase of 99 members over that of the previous year. The average increase in membership for the past five years was 175 a year. Many of the delinquents would come back but it was evident that active recruiting would have to be kept up and greater efforts made to bring in new members. The society represented a little over 50 per cent. of the entire profession of the State, but there were certainly many men who should belong and did not The honor list of county societies whose membership for 1912 was fully paid up was as follows: Chautauqua, Greene, Ontario, Orleans, Queens-Nassau, Schoharie, Sullivan, Tioga, Washington, and Wayne. The attention of the House of Delegates was especially directed to the report of the Committee on Revision of By-Laws and it was earnestly hoped that the subject would be studied by all before the meeting at which the report was to be presented.

**Report of the Treasurer.**—Dr. ALEXANDER LAMBERT of New York presented this report which consisted in the certified balance sheets of the Society and showed that excess of expenditures over income for the year 1912 was $1,306, while the income was $21,940. This excess of expenditure was partially offset by the excess of income of the previous year of $850.

**Report of the Council.**—Dr. WISNER R. TOWNSEND of New York presented this report which recorded the meetings held during the year, the minutes of which had been published in the *New York State Medical Journal*. During the year the secretary had sent a letter to every county society in the State asking for data in regard to the subject of illegal practitioners in their counties. The replies received showed that in fifteen counties they had no illegal practitioners, in two counties they had but two illegal practitioners, in four counties they had a few chiropractics, phisio-therapeutists, druggists prescribing, etc., in two counties they had four illegal practitioners. Erie County stated that it was impossible to even estimate the number of irregular practitioners. One county had several hundred illegal practitioners, and nineteen were prosecuted during the year, while another county reported ten or twelve illegal practitioners. The New York County Medical Society had prosecuted eighty-five at an expenditure of about $6,000. The secretary said that he had interviewed the attorneys for the State and County societies and they were agreed that it would be a very expensive undertaking to establish a central office to take charge of this work for the entire State, that it would be much better for the local county societies to handle this subject themselves. The Council believed that this matter was worthy of further investigation and it was suggested that the entire subject be referred to a committee of three to be appointed at this meeting.

**Report of the Committee on Publication Appointed by the Council.**—Dr. WISNER R. TOWNSEND of New York submitted this report in connection with that of the Council. The Committee on Publication consisted of Drs. S. W. S. Toms, chairman; Floyd Crandall, Samuel E. Getty, Alexander Lambert, and Henry G. Webster. The duties of this committee consisted in the publication of the *New York State Journal of Medicine* and the "Medical Directory of New York, New Jersey, and Connecticut." In accepting advertisements the *Journal* was conforming to the requirements of the American Medical Association and this compliance had restricted the advertising matter and materially lessened the income from the *Journal*. The cost of publication, as compared with 1911, showed an increase of $1,306. This was due to an increase in the number of pages of reading matter as well as to a limitation of the advertisements. Eight thousand copies were issued monthly, which was an increase of two hundred per month as compared with 1911. The Directory was issued in October, 1912, and work on the next year's issue was under way. The next issue would contain a complete list of the examiners in lunacy for the entire State as well as of those registered in New York County. The committee would be pleased to receive any further suggestions for the improvement of the book.

**Report of the Committee on Public Health.**—Dr. JOSHUA M. VAN COTT of Brooklyn submitted this report which expressed satisfaction with the growing interest of physicians throughout the State in clinical laboratory diagnostics and their demand for local facilities for such work. It was the feeling of the committee that the State Society should take an active part in endeavoring to procure legislation for the establishment of local laboratories at convenient points throughout the State. The committee further felt that the State Society might well send annual communications to the legislature commending such of its actions as it could approve and recommending such further legislation as, in its judgment, might be deemed advisable. In regard to the recent action of the Governor, and the report of the special health commission, the Committee thought that the time was not ripe for action.

**Report of the Committee on Legislation.**—Dr. Robert P. Bush of Horseheads submitted this report. He stated that the legislative work of the committee during the session of 1912 was very much less arduous than it was in the year 1911, as the field of operation chosen by the opponents to scientific research by means of animal experimentation, and those opposed to the vaccination laws, was the Assembly instead of the Senate. There were three slightly different antivivisection bills introduced. Evidently the speaker wished to give these advocates a fair chance, for the bills were referred to three different committees. He ignored the Committee on Public Health to which these bills should reasonably be referred. The Committee on Ways and Means and that on General Laws promptly reported the bills adversely. The reports were agreed to by the Assembly and they were killed. The Codes Committee decided not to report the bill referred to it. The two anti-vaccination bills went to the Committee on Public Health, and no further. The bill establishing a State School of Sanitary Science at Cornell University passed both houses but was again vetoed by Governor Dix. Bills were introduced during the year on the following subjects: To compel the hotels to furnish bed sheets at least nine feet in length so that they might be turned over and engage germs that might be incubated in the quilts and coverlids. To require all mattresses, pillows, etc., to bear a label showing the kind and quality of material used in their manufacture, whether new or second handed, etc. To compel the proprietors of public lavatories to furnish individual towels. Forbidding any railroad company to permit to be discharged from any of its cars any solid or liquid excreta within any drainage area or water shed, as designated by the State Commissioner of Health. None of these passed the Legislature; some of them should be enacted. The two bills which became laws were those prohibiting medical schools from matriculating students who were deficient in any part of the educational requirements, and a law providing for the creation of a commission to examine and, if need be, to protect society by the sterilization of degenerates, perverts, feeble-minded so that the class which was providing the largest item of expense which the State had to meet should not be able to propagate their kind, which at present was multiplying far in excess of the normal population. Two propositions had been presented by the Committee as being proper subjects for legislation, neither of which was endorsed by the Society: First, that the medical laws should be amended so as to prohibit nurses from administering anesthetics. Second, to provide that licensed physicians, who violated the code of ethics by advertising miraculous cures by consulting with illegal practitioners, etc., should be disqualified. This Committee held that the Society would do better to exercise its influence in enforcing the laws hitherto enacted than in urging the passage of others which would become dead letters. To this end they suggested that the House of Delegates appoint a committee to formulate a method of procedure by which the laws on the statute books might be enforced.

**Report of the Committee on the Regulation of the Introduction of Medical Expert Testimony.**—Dr. Dwight H. Murray of Syracuse submitted this report, which stated that no bill had been introduced into the Legislature last year because the Chairman of the State Bar Committee, who seemed to have assumed control of this matter, did not see fit to take it up. At a meeting of the committee the chairman was instructed to consult a constitutional lawyer who knew how to draw up a proper bill, and have one drafted for criminal cases only, meeting constitutional objections if possible. This course was now being followed and the committee hoped to have a bill drafted and to make an effort to get it passed.

**Report of the Committee on Scientific Work.**—Dr. Thomas J. Harris of New York submitted this report, which announced that the plan pursued last year would be followed at the present meeting. There would be five sections: Section on Medicine, Section on Surgery, Section on Nose, Throat, and Ear, Section on Obstetrics and Gynecology, and Section on Diseases of Children.

**Report of the Committee on Prize Essays.**—Dr. A. Vander Veer of Albany reported for this committee by giving the history of Dr. Merrit H. Cash who had given $500 in 1861, the interest of which was to be used as a prize for the best original essay on such medical or surgical subject as might be designated by a committee of the society. From 1867 on few prizes had been awarded and at one time the society offered to increase the amount up to $100. It was decided that the society did not have the right to make such disposal of its funds. Interest had accrued which had been added to the principal. As a result of the committee's consultation with the counsel it had been decided that the Merrit H. Cash prize would be awarded every two years, beginning with the annual meeting of 1914, and that the prize would consist of $100. This year the prize had been awarded to Dr. William Kirk of Troy and Dr. George L. Rodenberg of New York had received honorable mention. The report then gave the correspondence with Dr. Lucien Howe which led to the establishment of the Lucien Howe prize of $1,500. The conditions under which the income from this amount became available were given. The committee felt that $100 or whatever interest had accrued might be awarded annually. The prize was to be given for the best original contribution to their knowledge of some branch of surgery, preferably ophthalmology, and competition was not restricted to members of the State Society. The committee felt that while it was in their power to designate titles, keeping within the meaning of the gift, yet they would prefer to hear further from Dr. Howe regarding his wishes. The committee invited contributions to these funds, believing that in this way interest would be stimulated.

**Report of Committee on Experimental Medicine.**—Dr. William H. Park of New York submitted this report which gave the experience of the committee with the three antivivisection bills referred to in the report of the Committee on Legislation. This report stated that in past years it had been the custom of legislative committees not to make formal report to the Assembly expressing disapproval of antivivisection bills, even when such bills were disapproved. The prompt, positive vote of disapproval in all of the three cases of the past year, with the subsequent report to the Assembly, and in two cases the formal concurrence of the Assembly in the report, were evidence that the committee had felt less sympathy than ever before with antivivisection measures. The victory for scientific medicine had been correspondingly greater. The committee expressed the belief that its continued vigilance and activity in these various ways had been of material service in safeguarding the humane work of medical experimenters. It earnestly hoped that the members of the profession throughout the State would use their utmost efforts to keep clearly before the minds of the public and especially of the legislators the folly and injustice of hampering in any way the magnificent work which medical research was doing to prevent and relieve the sufferings of mankind and incidentally of dumb animals.

**Report of Committee on Revision of By-Laws.**—This committee which was appointed at the last annual meeting presented its report comprising the proposed amendments and changes in the by-laws. It had been the aim of the committee to make as few changes as possible, and those were based upon experience of over seven years under the present by-laws. These by-laws, as revised by the committee, with a few minor changes, were adopted by the House of Delegates.

**Report of the Counsel.**—Mr. James Taylor Lewis of New York submitted this report. He stated that there were no appeals pending and no verdict had been rendered against any member of the State Medical Society, defended by him during the past twelve years. In this connection he said that it was important that he should report with reference to the weakness of some of the members of the State Society in applying for and securing insurance against malpractice suits. This was deplorable and he recommended that hereafter no physician who was insured in any fidelity company be defended by the State Society. It was against the theory of the establishment of this malpractice defense by the State Society, the insurance companies benefited by the State Society's efforts; the question whether or not an expert should be paid by the State Society or the insurance company recurred, and altogether it was an unwise position for the State Society to take in any event. Organized malpractice defense as conducted by this society should be more publicly and widely disseminated. It should be brought to the attention of the belligerent patients and if the doctor had done what he considered proper he would not be subjected to blackmail under any consideration. He had been opposed to this publicity for many years, but the increase of new suits during the past year or two had made him feel that more publicity would be of benefit. The profession was largely to blame for this increase. Too many times it happened that the physician who was called in to supplement the work initiated by the unfortunate defendant had said something in depreciation of the original effort. There was hardly a case that was not attributable to some such word or act on the part of the new doctor. A large percentage of cases brought during 1911 had never been brought on for actual trial. Indeed, in 1912, but nine cases were actually tried in court, and

four were otherwise disposed of without going into court, plaintiffs having abandoned their cases at the last moment. The ever-broadening influence of the State Society was making itself felt in many directions and through many channels. Sister State societies were inquiring as to the success of the malpractice defense, and adopting the procedure, and the counsel had continued as hitherto to answer such legal questions as were propounded on the various subjects which were presented. Mr. Lewis gave a list of the thirty-six cases begun during the year 1912.

Reports of the councillors of the eight district branches were submitted.

**Supplementary Report of the Committee on the Regulation of Medical Expert Testimony.**—Dr. DWIGHT H. MURRAY of Syracuse read the following bill, which he stated had been introduced into the Legislature and would be voted upon by the Assembly during the present week: "In a criminal action or proceeding or in a special proceeding by the State writ of habeas corpus or certiorari to inquire into the cause of detention in which soundness of mind of a person is the issue, the court in which the proceeding is pending may appoint not more than three disinterested competent physicians to examine such person as to his soundness of mind at the time of examination. Each such examining physician may be sworn as witness at the instance of any party to the action or proceeding. The compensation of such examining physician for making such examination and testifying when certified by the presiding judge or justice of the court or judge or justice making the appointment shall be paid out of any funds available for the payment of and in the same manner as other court expenses."

**Time and Place of Next Meeting.**—The date set for the next meeting of the society was Tuesday, April 28, 1914. New York City was chosen as the place of meeting.

**A Communication from Congress.**—The President, Dr. WHITBECK, read a communication from the Department of the Interior in reference to a resolution presented to Congress by the American Medical Association, asking for an investigation of the physiological and therapeutic properties of the waters of Hot Springs, Ark., requesting the State Society to discuss the advisability of such a proceeding and to communicate its conclusions to the Department of the Interior. Similar requests had been made of other State societies.

The communication was referred to the Council with power to act.

**A Bronx County Society.**—The application for a charter creating a Bronx County Medical Society was referred to the committee with recommendations that the privilege of forming a new county society be granted to the members of the Medical Society of the State of New York residing in the Bronx, but not to any one medical society already in existence.

**Resolution to Lower Tariff.**—A resolution was adopted for presentation to Congress recommending that the tariff on surgical instruments and medical appliances be removed. Resolutions were introduced by the Erie County Society endorsing the plan of establishing a special degree in surgery corresponding to the F. R. C. S. in England, and also one condemning fee-splitting.

---

GENERAL SESSION.

*Tuesday, April 29—First Day.*

THE PRESIDENT, DR. JOHN W. F. WHITBECK, IN THE CHAIR.

**Invocation.**—The Reverend R. R. M. CONVERSE of Rochester opened the meeting by prayer.

**Address of Welcome.**—Dr. WESLEY T. MULLIGAN, Chairman of the Committee on Arrangements, made this address.

**Address of Welcome.**—The Honorable HIRAM H. Edgerton, Mayor of Rochester, welcomed the Society to the city. He congratulated the city on its good fortune in having the Society within its gates. He congratulated the doctors in that they were able to take advantage of the hospitality of the city and share in the benefits to be derived from the scientific meetings, and he congratulated those who remained at home who were thus given a respite and some chance for their lives.

**Annual Oration on Medicine.**—Professor JOHN G. ADAMI of McGill University, Montreal, made this address, choosing as his subject "Certain Elementary Concepts in Education Applied to Medicine." (To appear later.)

**Address of the President.**—Dr. JOHN F. WHITBECK of Rochester said that he had thought it wise to have Dr. Adami make the principal address of the morning instead of making it himself as had been the custom of former presidents. He drew an analogy between the Medical Society and a ship and said that Longfellow's apostrophe to the Ship of State was applicable on this occasion. He then recited the verses "Thou, too, sail on, O, ship of State, etc."

---

SECTION ON MEDICINE.

*Tuesday, April 29—First Day.*

DR. DELANCEY ROCHESTER OF BUFFALO IN THE CHAIR.

**Pain and Other Clinical Manifestations of Myocarditis.**—Dr. ALEXANDER LAMBERT of New York read this paper. He said that one frequently heard that it was only at the post mortem that myocarditis could be accurately diagnosticated, and this idea seemed to be the remnant of the old idea that when the lesions in the valves had been accurately estimated, that was all there was to do in considering cardiac disease. The graphic methods of registering the occurrences in the cardiac cycle, which had developed so enormously in the last ten years, had very greatly altered the point of view of the profession. But there still remained the idea that outside of these special instruments of precision it was not possible to have an accurate estimate of the condition of the heart muscle. Even with these instruments the kind of degeneration that was present in the heart muscle did not appear and they must fall back on the clinical observations of the different forms of myocardial degeneration that were most likely to occur with certain of the general diseases, and to estimate from other signs and symptoms than the graphic method what was the form of myocarditis present.

It had been his belief for a number of years that cardiac pain was a much earlier symptom in cardiac symptoms than was generally believed. The majority of physicians did not pay much attention to precordial pain unless it radiated down the left arm; then they believed it was due to some form of angina, and if the patient did not have attacks of breathlessness, or did not drop down with it, they were prone to call it pseudo-angina, especially if it occurred in women. Most men were not willing to call anything angina unless it had the fear of impending death connected with its occurrence; but they believed that all other pains occurring in the heart were false angina unless the fear of death came from it. He thought it might be well for certain reasons to limit the name of angina pectoris to only the very serious cases of cardiac pain and in which the attacks were so severe that death might occur at any time. But it would seem to him that it was vastly better to recognize that cardiac pain occurred with various degrees of intensity, and that there might be pain in the heart of slight intensity without fear of impending death, and as an early symptom of myocardial changes. These pains might occur in various areas on the chest wall, or on the arm and, though they might consider them as reflex or referred pains, were of cardiac origin; they should be considered as such and treated as such. Mackenzie had done a great service in calling attention so accurately to the fact that the heart had no nerves or means of expressing pain to the muscular wall itself, and the nerves of the heart could not produce the sensation of pain. Vibrations radiating from the heart could, however, through whatever nerves they went, reach the segments of the spinal cord and radiate causing vibrations, so that the expression of pain occurred out in the nerves of the skin in which they were in the habit of feeling that sensation. Mackenzie had shown that some cardiac pain was referred to the area supplied by the second and third cervical segments, and ran down to the heart through the vagus. This would account for the occipital headaches and tenderness of the sternocleidomastoid and trapezius muscles which were sometimes present. The distribution of the pain and hyperesthesia, according to Head, bore a close relation to the chamber of the heart most affected. Pain, from whatever cause, starting in the heart, went by whatever channel to some segment from the third and fourth cervical, skipping the fifth, sixth, seventh, and eighth, again reappearing in the first thoracic down to the eighth. It had long been recognized that pain down the arm was due to a referred cardiac pain. But it was the failure to have recognized the extensive area in which pain from the heart occurred that had made so many mistakes possible in considering what cardiac pain was. It seemed to Dr. Lambert that the most frequent position of pain was some position between the fourth and sixth ribs over the pectoral muscle near the nipple. This was the one in which there was frequent tenderness but frequently the hypersensitiveness of the skin and the hyperalgesia remained for a day or two after the actual pain had ceased. It was not uncommon for pain in the left wrist

to be treated as gout or rheumatism which, in reality, was the first expression of myocarditis. It was his opinion that various pains of moderate degree coming from the heart were so common on the left side of the chest and in the left arm in the areas he had designated, that the wisest method of thought, when in the presence of pain in these areas, was to realize that the only safe method was to start with the supposition that such pains were most probably cardiac and proceed to exclude other possible diagnosis, and not exclude cardiac pain and wonder what the diagnosis was which heretofore had been the usual method of procedure.

Shortness of wind was one of the early signs of myocardial degeneration. It was a very striking thing to see the number of alcoholics after a debauch who would complain of an intense aching pain in the precordial region. It was not the old alcoholic in whom one would expect aortic arteriosclerosis and coronary disease and a naturally starved cardiac muscle, but it was in the rugged, vigorous, young looking alcoholic that these pains were most commonly complained of, as if the poisoning of the alcohol and the over-exertion committed in the spree had produced an aching pain from the degenerated muscle. It was a very striking feature in syphilitic endocarditis and in syphilitic aortitis to see how common were these pains and how quickly they would cease following a small dose of salvarsan.

**The Symptoms and Diagnosis of Involvement of the Heart in Syphilis.**—Dr. Harlow Brooks and Dr. John H. Carrol presented this paper. The study was based on a series of 200 selected cases from private consultation and hospital practice. In 75 instances the clinical study was concluded with autopsies. Absolute diagnosis of the existence of syphilis in each instance was insisted upon by the Wassermann reaction, by associated syphilitic lesions, by the history, and by anatomical studies in the autopsy cases. Absolute diagnosis of the luetic character of the cardiac lesions was demonstrated by cure or amelioration of the signs and symptoms under specific treatment or by the anatomical study post mortem. Eleven cases occurred during the secondary stage of the infection. The remaining cases represented tertiary and quaternary periods. It was definitely shown that cardiac involvement might appear early in the secondary period and three post-mortem cases were cited to demonstrate this point absolutely in addition to the clinical cases. The study would seem to indicate that the progress of cardiac involvement was more rapid in females, especially in young women. Probable reasons for this fact were advanced. Fertility in married patients did not differ greatly from the normal, but exact data as to the condition of the issue could not be accurately obtained. Cardiovascular symptoms were complained of in 164 instances, in the remaining cases either the lesion caused unexpected death or was found accidentally on physical examination or at autopsy. The most frequent symptom appeared to be dyspnea. Pain in the precordium was a frequent and very important symptom; it was often manifest in very early stages and was rarely entirely absent. Frequently it took on a true anginal character; 9 per cent. of cases studied showed this type. Precordial tenderness was frequent. Cyanosis of greater or less degree was present in over 50 per cent. of the cases selected for study. Insomnia was quite frequent. Although it was admitted that the symptoms of heart involvement in lues could not be definitely distinguished from the associated signs of syphilitic aortitis in so far as possible, cases showing this lesion to recognizable marked degree were eliminated from this series. Actual decompensation demanding early cardiac treatment was present in 89 cases. It was important to note that even in these instances greatest benefit followed specific treatment. Endocarditis appeared to play a secondary rôle as regards importance to disease of the myocardium. The most frequent endocardial lesions were combined, one of the aortic and mitral valves; next in frequency was pure aortic disease which was found in 42 cases. Studies of the blood pressure did not appear to advance general information in regard to the complication. In the diagnosis the fallacy of the history was pointed out and the importance of associated luetic signs and symptoms, the great importance of the Wassermann reaction and the therapeutic test was particularly dwelt upon. The fact that a Wassermann reaction might persist in a perfectly cured case was apparently shown and the prognostic value of the reaction would therefore appear to be in question. The paper terminated with a summary of the above statement in the form of conclusions and with the expression of thanks to those of their associates who had contributed to the study by suggestions and cases.

**Selective Drug Action on the Nervous System as an Aid to Diagnosis.**—Dr. Nelson G. Russell and Dr. Carroll J. Roberts of Buffalo presented this communication. They stated that the so-called animal nervous system which supplied the organs of sense and all voluntary muscles was to be distinguished from the vegetative system, which supplied the smooth muscle of viscera, certain cross-striped muscle and the secreting portion of glands. The vegetative system was further divided into the sympathetic and the autonomic systems. The autonomic system was made up of a cranial portion, a bulbar portion, and a sacral portion. Owing to the importance of the vagus, the chief nerve of the system, the autonomic system was also called the extended vagus, and the study of the drug reactions of this system was called vagatonic. To organs mentioned by them they had two sets of nerve fibers which were physiologically antagonists and a balance was theoretically necessary for the normal functions of the organs to be carried on. Each system was acted upon selectively by certain drugs. Thus pilocarpine acted as an irritant to the autonomic system and produced the same effects as electrical stimulation. Atropine acted as a depressor of the autonomic system and counteracted the effects of pilocarpine. Adrenalin stimulated the sympathetic system, but as yet they did not know of a drug that had a depressing action on the sympathetic system. Pilocarpine might in certain susceptible individuals produce, through stimulation of the autonomic system, certain symptoms, and one so susceptible was called a "vagatoniker." According to Eppinger and Hess of Vienna many of the so-called cases of hysteria and neurasthenia and the neuroses were, as a matter of fact, due to irritability of the autonomic system and they supported their claims by abundant clinical proof. The method of procedure carried out in the investigation of cases was described. The practical application of the facts learned from a positive reaction was that any symptom produced by an injection of 0.01 gm. of pilocarpine, referable to an irritable autonomic system, would be relieved by atropine, the depressor of the autonomic system, and a case was reported to illustrate this point. The paper was presented with the hope that some of the points contained might be useful in determining the exact status of certain cases that showed vagus or sympathetic disturbance.

**Cardiac and Arterial Decompensation: Prevention and Treatment.**—Dr. Louis Faugères Bishop read this paper. He said that compensation was defined by Stedman's "Medical Dictionary" as: "The supplying of a deficiency; the making up in one part for a loss in another. Specifically, the maintenance of the circulation, in cases of cardiac valvular defect, by hypertrophy with resulting increased force of the contractions of the heart muscle." It had latterly been suggested, but not generally admitted, that arterial compensation consisted in an increase in the structures composing the arteries to accommodate a more active function demanded by high blood pressure, which, in turn, might be occasioned by functional difficulties, more especially of the kidneys. The causes of broken compensation in the heart might be a deterioration of the healthfulness of the heart muscle because it was "made sick" by poisons that reached it through the circulation, or lost its reserve through exhaustion or neglect of exercise. There were three topics to be considered: (1) Pure cardiac compensation in non-progressive valvular disease. (2) Arterial compensation maintaining a necessary increase in blood pressure. (3) Combined cardiac and arterial compensation where valvular defects existed with kidney or other demands for pressure. Instances of the first form of compensation have been quite frequent in his experience with young persons. They gave the history of some damaging disease and presented themselves with murmurs and a compensating hypertrophy of the heart. They should be wisely advised for they were plastic material for the easy creation of chronic invalids on the one hand, or the development of useful lives on the other. They should be told that their problem was the same as the problem of any of their healthy contemporaries who were preparing for an athletic contest, namely, the maintenance of the heart in the best possible condition of health and efficiency. After being warned against things demanding strain, they should be urged that they could not afford to neglect other forms of exercise. Tennis, horseback riding, swimming, and walking were all appropriate. They must be taught to respect their wind and let it be the indication for the moderation or cessation of exercise. Many would show a tendency to defect of circulation in the liver and do better on a few-proteins diet. The blood would often be found too abundantly supplied with red cells, so that tonics and forced feeding led to a condition of congestive plethora that was not desirable, and tended toward autointoxication. Those

who were compelled to work sometimes did better than those who were unwisely guarded. Plain living, with abundant exercise, devoid of strain, was the ideal state of the young person with pure cardiac compensation. It was one of the pleasures of the specialist to be able to reassure the parents and the young people themselves, and put them on the plane of average individuals. The treatment of broken compensation with uncomplicated valvular disease in young persons required a study of its cause, which was often enough found to be muscular strain that had been out of proportion to the power of the crippled heart, particularly when there had been dissipation. Prolonged rest might be necessary, and sometimes the occasional use of digitalis was required. The diet should be liberal, and the auxiliary use of iron, arsenic, and strychnine as a tonic was allowable if there was true anemia or nervous depression. In these young people they did not have to contend with many contraindications to such measures as were found in older people. When compensation was restored, out-of-door exercise was necessary for its maintenance. Simple arterial compensation was found in persons who had undergone some damage to the kidneys and blood-vessels, most often through some infection, but occasionally through metallic or food poisoning. These were ordinarily first seen when a little older than those with pure cardiac compensation, and in their care present a somewhat different problem, though, hygienically, they work out much the same. A careful study would usually show that they were unable to deal successfully with some of the ordinary protein foods. This amounted to a subsymptomal sensitiveness. It might be meat, eggs, fish, or two of these classes of protein. Hence, the selection of proteins suitable to the individual was of extreme importance. There was no chemical test that had been worked out up to the present time, so they were driven to indirect means for the determination. Tradition and popular prejudice made meat, particularly red meat, least desirable; but some tolerated meat, and could not tolerate eggs; and others showed under investigation that fish was their insidious enemy. The study of the effect of special foods on blood pressure helped, but if the sensitiveness was very great, on the withdrawal of all classes of proteins, that which was craved most would often be found to be the one at fault, on the same principle as alcohol was craved by the alcoholic. Protein food, to which a person was sensitive and which had become an habitual poison, acted as a stimulant and was missed. When withdrawn, it led to a false sense of weakness that really did not represent a lack of physical strength. In the care of arterial compensation, the few-protein diet would be found most desirable and much more easy to maintain than the low-protein diet. It consisted of allowing as much as was desired of a few selected proteins, and absolutely avoiding the others. Arterial compensation could thus be satisfactorily maintained over long periods of time. Broken arterial compensation in its simplest form was found in the subjects of high blood pressure, who, through injudicious treatment, the action of depressor poisons or severe nervous shock, underwent a loss of vascular tone leading to interference with circulation in the kidneys and other organs. There was an accumulation of blood in the splanchnic area and a general condition which was often described as "auto-intoxication." These responded to outdoor exercise, simplification of diet, intestinal hygiene, and the use of vascular tonics, theobromine being one of the most valuable. While in the second class, the heart was always slightly involved, in the third class it was sometimes difficult to say which was primary—the arterial or the cardiac condition. They found decided valvular defects with a considerably elevated standard of blood pressure. The care of these persons involved the principles of the other two classes of compensation. The treatment of broken compensation in combined cardiac and arterial disease, which corresponded closely to secondary low blood pressure, which the author had so often described in previous communications, was the most serious problem in cardiovascular disease. The condition developed after years of compensatory life, and the sufferer presented dilatation of the heart with feeble valvular orifices and pathological relaxation of the blood vessels causing dropsy, edema of the lungs, congestion of the liver, impaired cerebral circulation, and partial paralysis of the kidneys. In this condition, persons were always highly sensitive to many proteins, even often to the proteins of milk. Secondary low blood pressure was always present, though, at times, the blood pressure measurement was misleadingly high on account of local vascular spasm. Unfortunately, they often came to the specialist's notice when the situation had been complicated by the liberal, but not always wise, administration of inappropriate drugs. The limits of the paper did not allow the full discussion of so serious a condition. The principles of treatment in his own hands, Dr. Bishop said, involved the thorough clearing up of the intestinal condition by the administration of at least an ounce of castor oil on three successive occasions at intervals of 48 hours; the thorough digitalization of the heart; the withdrawal, at first, from the diet of eggs, fish, meat, and soups, and, in a large measure, of milk; allowing bread and butter, vegetables, and cereals; and as soon as possible the commencement of graduated exercise, leading up to as much of an outdoor life as possible, and gradually to a more liberal diet.
